Wildland Fire in Ecosystems

Effects of Fire on Flora

Abstract

Brown, James K.; Smith, Jane Kapler, eds. 2000. Wildland fire in ecosystems: effects of fire on flora. Gen. Tech. Rep. RMRS-GTR-42-vol. 2. Ogden, UT: U.S. Department of Agriculture, Forest Service, Rocky Mountain Research Station. 257 p.

This state-of-knowledge review about the effects of fire on flora and fuels can assist land managers with ecosystem and fire management planning and in their efforts to inform others about the ecological role of fire. Chapter topics include fire regime classification, autecological effects of fire, fire regime characteristics and postfire plant community developments in ecosystems throughout the United States and Canada, global climate change, ecological principles of fire regimes, and practical considerations for managing fire in an ecosystem context.

Keywords: ecosystem, fire effects, fire management, fire regime, fire severity, fuels, habitat, plant response, plants, succession, vegetation

The volumes in "The Rainbow Series" will be published from 2000 through 2001. To order, check the box or boxes below, fill in the address form, and send to the mailing address listed below. Or send your order and your address in mailing label form to one of the other listed media. Your order(s) will be filled as the volumes are published.

- ☐ RMRS-GTR-42-vol. 1. **Wildland fire in ecosystems: effects of fire on fauna.**
- ☐ RMRS-GTR-42-vol. 2. **Wildland fire in ecosystems: effects of fire on flora.**
- ☐ RMRS-GTR-42-vol. 3. **Wildland fire in ecosystems: effects of fire on cultural resources and archeology.**
- ☐ RMRS-GTR-42-vol. 4. **Wildland fire in ecosystems: effects of fire on soil and water.**
- ☐ RMRS-GTR-42-vol. 5. **Wildland fire in ecosystems: effects of fire on air.**

Preface

In 1978, a national workshop on fire effects in Denver, Colorado, provided the impetus for the "Effects of Wildland Fire on Ecosystems" series. Recognizing that knowledge of fire was needed for land management planning, state-of-the-knowledge reviews were produced that became known as the "Rainbow Series." The series consisted of six publications, each with a different colored cover, describing the effects of fire on soil, water, air, flora, fauna, and fuels.

The Rainbow Series proved popular in providing fire effects information for professionals, students, and others. Printed supplies eventually ran out, but knowledge of fire effects continued to grow. To meet the continuing demand for summaries of fire effects knowledge, the interagency National Wildfire Coordinating Group asked Forest Service research leaders to update and revise the series. To fulfill this request, a meeting for organizing the revision was held January 4-6, 1993, in Scottsdale, Arizona. The series name was then changed to "The Rainbow Series." The five-volume series covers air, soil and water, fauna, flora and fuels, and cultural resources.

The Rainbow Series emphasizes principles and processes rather than serving as a summary of all that is known. The five volumes, taken together, provide a wealth of information and examples to advance understanding of basic concepts regarding fire effects in the United States and Canada. As conceptual background, they provide technical support to fire and resource managers for carrying out interdisciplinary planning, which is essential to managing wildlands in an ecosystem context. Planners and managers will find the series helpful in many aspects of ecosystem-based management, but they will also need to seek out and synthesize more detailed information to resolve specific management questions.

— The Authors
October 2000

Acknowledgments

The Rainbow Series was completed under the sponsorship of the Joint Fire Sciences Program, a cooperative fire science effort of the U.S. Department of Agriculture, Forest Service and the U.S. Department of the Interior, Bureau of Indian Affairs, Bureau of Land Management, Fish and Wildlife Service, National Park Service, and U.S. Geological Survey. We thank Marcia Patton-Mallory and Louise Kingsbury for persistence and support.

The authors wish to thank the following individuals for their suggestions, information, and assistance that led to substantial technical and editorial improvements in the manuscript: Stephen Arno, Andrew Applejohn, David Bunnell, Tammy Charron, Lisa Clark, Scott Collins, Bonni Corcoran, Luc Duchesne, Colin Hardy, Mick Harrington, Janet Howard, Bill Leenhouts, Jim Menakis, Melanie Miller, Penelope Morgan, Rob McAlpine, Carmen Mueller-Rowat, Ron Myers, Phil Omi, Pat Outcalt, Tim Paysen, Kevin Ryan, Dennis Simmerman, Jim Snyder, Peter Stickney, Ann Murray Strome, Fred Swanson, David VanLear, Dale Wade, Phil Weatherspoon, Mike Weber, and John Zasada.

Summary

This state-of-knowledge review about the effects of fire on flora and fuels can assist land managers in planning for ecosystem management and fire management, and in their efforts to inform others about the ecological role of fire. Chapter 1 presents an overview and a classification of fire regimes that is used throughout the report. Chapter 2 summarizes knowledge of fire effects on individual plants, including susceptibility to mortality of aerial crowns, stems, and roots; vegetative regeneration; seedling establishment from on-site and off-site seed sources; seasonal influences such as carbohydrates and phenological stage; and factors affecting burn severity.

Five chapters describe fire regime characteristics such as fire severity, fire frequency, and fire intensity, and postfire plant community responses for ecosystems throughout the United States and Canada. Typical fuel compositions, fuel loadings, and fire behavior are described for many vegetation types. Vegetation types including Forest-Range Environmental Study (FRES), Kuchler, and Society of American Foresters (SAF) types are classified as belonging to understory, mixed, or stand replacement fire severity regime types. The severity and frequency of fire are described for the pre-Euro-American settlement period and contrasted with current fire regimes. Historic fire frequencies ranged from a fire every 1 to 3 years in some grassland and pine types to a

fire every 500 to 1,000 years in some coastal forest and northern hardwood types. In many vegetation types characterized by understory fire regimes, a considerable shift in fire frequency and fire severity occurred during the past century. Successional patterns and vegetation dynamics following disturbance by fire, and in some cases related grazing and silvicultural treatments, are described for major vegetation types. Management considerations are discussed, especially for the application of prescribed fire.

A chapter on global climate change describes the complexity of a changing climate and possible influences on vegetation, fuels, and fire. The uncertainty of global climate change and its interactions with vegetation means expectations for fire management are general and tentative. Nonetheless, manipulation of wildlands and disturbance regimes may be necessary to ensure continual presence of some species.

The last chapter takes a broader, more fundamental view of the ecological principles and shifting fire regimes described in the other chapters. The influences of fire regimes on biodiversity and fuel accumulation are discussed. Strategies and approaches for managing fire in an ecosystem context and sources of technical knowledge that can assist in the process are described. Research needs are broadly summarized.

James K. Brown

Chapter 1: Introduction and Fire Regimes

At the request of public and private wildland fire managers who recognized a need to assimilate current fire effects knowledge, we produced this state-of-the-art integrated series of documents relevant to management of ecosystems. The series covers our technical understanding of fire effects, an understanding that has expanded considerably since about 1980, along with an awareness that fire is a fundamental process of ecosystems that must be understood and managed to meet resource and ecosystem management goals. The “Rainbow Series” of documents stresses concepts and principles, provides an entry into the relevant literature, and discusses management implications. The volumes in the series are intended to be useful for land management planning, development of environmental assessments and environmental impact statements, training and education, informing others such as conservation groups and regulatory agencies, and accessing the technical literature.

Knowledge of fire effects has attained increased importance to land managers because fire as a disturbance process is an integral part of the concept of ecosystem management. Fire—a disturbance that initiates change—affects the composition, structure, and pattern of vegetation on the landscape. Disturbance is

necessary to maintain a diversity of living things and processes. The old idea of plant communities and their broader ecological systems reaching equilibrium is being rejected by modern ecologists and resource managers (Botkin 1990; Morgan and others 1994).

Aldo Leopold (1949) recognized the principle of ecosystems decades ago, but it has only recently received widespread recognition as an important process to guide management of wildlands. Although the variety of governmental and private organizations responsible for management of natural resources disagree on an exact definition of ecosystem management, the goal of sustainability is central to most approaches (Christensen and others 1996). This goal focuses on delivery of goods and services. Ecosystem management defined by Christensen and others (1996) is *management driven by explicit goals, executed by policies, protocols, and practices, and made adaptable by monitoring and research based on our best understanding of the ecological interactions and processes necessary to sustain ecosystem structure and function*. This definition puts the primary focus on sustainability of ecosystem structures and processes necessary to deliver goods and services.

Ecosystem management broadens the focus of management from patches or stands to landscapes of variable scale. It moves the focus from individual ecosystem parts such as timber, water, range, fish, and wilderness, to how the parts fit together and function as a whole (Bormann and others 1994). It embodies other concepts such as conservation of biodiversity, sustained yield of multiple resources, and ecosystem health (Salwasser 1994). A guiding premise for sustaining ecosystems and protecting biodiversity put forth by Kaufmann and others (1994) is to manage ecosystems to conserve the structure, composition, and function of all elements, including their frequency, distribution, and natural extinction. Fire effects are woven through all aspects of this premise. An ecosystem can be defined as simply a place where things live (Salwasser 1994) or in more detailed terms that relate the interaction of organisms and physical environment through a flow of energy (Bormann and others 1994). Ecosystems contain components such as plants, vegetative communities, and landforms, and processes such as nutrient cycling. The dynamic nature of ecosystems and the scale of landscape patterns and processes are fundamental ecosystem characteristics that managers must consider in integrating knowledge of fire into the management of ecosystems.

Fire is a dynamic process, predictable but uncertain, that varies over time and the landscape. Fire has shaped vegetative communities for as long as vegetation and lightning have existed on earth (Pyne 1982). Recycling of carbon and nutrients depends on biological decomposition and fire. In regions where decay is constrained by dry and cold climates, fire plays a dominant role in recycling plant debris. In warmer, moist climates, decay plays the dominant role (Harvey 1994).

Lightning as a cause of fire over geologic time is widely appreciated. But humans also have been a major source of ignition, having used fire for various purposes during the past 20,000 years (Wright and Bailey 1982) and beyond. The pervasive influence of intentional burning by Native Americans during the past several centuries is probably not fully appreciated (Denevan 1992; Gruell 1985a). Human influence was particularly significant in grasslands and those communities bordering grasslands (Wright and Bailey 1982). Historically, fire caused by all ignition sources occurred over large areas covering more than half of the United States at intervals of 1 to 12 years; and fire occurred at longer intervals over most of the rest of the country (Frost 1998).

The land manager faces a complex challenge in managing fire to achieve beneficial effects and avoid unwanted results. Even attempts to eliminate harmful fire can over the long term cause undesirable consequences, such as increased risk of damaging fire

and declining ecosystem health (Covington and others 1994; Mutch and others 1993). Thus, it is imperative that the immediate and long-term effects of fire be understood and integrated into land management planning.

Flora and Fuel Volume

The purpose of the Flora and Fuel volume is to assist land managers with ecosystem and fire management planning and in their efforts to inform others about the role of fire and the basis for including fire as an ecosystem management practice. The geographic area covered in this series volume includes Canada and all of the United States and adjoining Caribbean areas. The contents focus on principles, generalities, and broad scale fire effects on flora rather than on detailed site specific responses. Vegetative response to individual fires can vary substantially depending on a host of factors involving characteristics of the fire, existing vegetation, site conditions, and postfire weather. The value and indeed challenge in preparing this volume was in providing a summary of fire effects that was meaningful over broad areas even in view of highly variable responses. Those wishing a more detailed explanation of fire effects on flora are referred to several textbooks on the subject (Agee 1993; Johnson 1992; Wein and MacLean 1983; Wright and Bailey 1982).

Chapter 2 covers autecological effects of fire. Chapters 3 through 7 are about regional fire regime characteristics and postfire development of plant communities. Chapter 8 reviews the potential for climate change and implications for fire management. Chapter 9 provides an overview of the ecological principles underlying fire regimes, shifts in fire regimes, and related management considerations.

The regional fire regime chapters are organized by the following biogeographic regions:

- Northern ecosystems
- Eastern United States forests and grasslands
- Western forests
- Western shrublands, woodlands, grasslands
- Subtropical ecosystems

Each plant community chapter is organized by fire regime type (understory, mixed, stand-replacement) and similar subheadings. First, the fire regime characteristics are described, including fire severity, fire frequency, fire size and pattern, and fuels and fire behavior. This emphasizes the commonality of vegetation types that have similar fire regime characteristics based on the dominant vegetation undergoing similar structural changes. Next, postfire plant communities are discussed with emphasis on temporal changes in vegetation and fuels. Pre-1900 and post-1900

subheadings are often used to help distinguish between succession occurring before and after organized fire suppression. The 1900 date is an approximation of when fire suppression effectively reduced the extent of wildfire. In some vegetation types knowledge is insufficient to determine whether successional patterns differ between the two periods. Last, management considerations are described involving silvicultural practices, prescribed fire, ecosystem restoration, and other aspects of planned disturbance for maintaining healthy ecosystems.

The word “fuels” refers to live and dead vegetation that can potentially contribute to combustion. Fuel quantities can vary from a small portion to all of the aboveground biomass depending on a number of fuel properties especially particle size, moisture content, and arrangement. Although vegetation biomass increases predictably with time because of perpetual photosynthesis, changes in fuel biomass over time can be highly irregular due to the tradeoff between annual increment and decay and properties affecting fuel availability. In this volume fuels are described generally in terms of accumulation and flammability. Some information on fuel loadings is presented primarily to show typical values or a range in values that characterize various vegetation types. Fuel loading models for major vegetation types can be found in the First Order Fire Effects Model (FOFEM), which provides quantitative predictions of tree mortality, fuel consumption, smoke emissions, and soil heating (Reinhardt and others 1997). More detailed knowledge can be found in the literature referenced throughout this volume.

Plant community fire effects are discussed for broad vegetation types. Forest and Range Environmental Study (FRES) ecosystem types (Garrison and others 1977), which cover the 48 contiguous States, are used at the broadest scale. Society of American Forester cover types (Eyre 1980) are also used especially for Canada and Alaska, and where more resolution of fire effects knowledge is needed. FRES ecosystem types are based on an aggregation of Kuchler’s (1964) Potential Natural Vegetation classes (American Geographical Society 1975). FRES, SAF, and Kuchler types that have similar fire regime characteristics are grouped to show synonymy (tables 3-1, 4-1, 5-1, 6-1, 7-1). Due to the subjective nature of defining vegetation types, some overlap occurs among types, particularly Kuchler and SAF types. For example, some SAF types may be reported in more than one Kuchler type. The correspondence of Kuchler and SAF types with FRES types is also described in the Fire Effects Information System User’s Guide (Fischer and others 1996).

Scientific names of plant species referred to by common names throughout the volume are listed in appendix A. Appendix B describes the succession

simulation models. And the glossary of fuel, fire, and plant reproduction terms is in appendix C.

Fire Regimes

“Fire regime” refers to the nature of fire occurring over long periods and the prominent immediate effects of fire that generally characterize an ecosystem. Descriptions of fire regimes are general and broad because of the enormous variability of fire over time and space (Whelan 1995). Classification of fire regimes into distinct categories faces the same difficulties and a dilemma that underlie any ecological classification. One difficulty is that putting boundaries around segments of biological processes that vary continuously involves some degree of arbitrariness. The dilemma is that for a classification to be useful to managers it must be practical and easily communicated, thus free of complexity. Yet to accurately reflect the nature of a biological process, such as response to fire, it must account for a complexity of interacting variables. A tradeoff between practicality and accuracy or between simplicity and complexity is required. The fire regime concept brings a degree of order to a complicated body of fire behavior and fire ecology knowledge. It provides a simplifying means of communicating about the role of fire among technical as well as nontechnical audiences.

Classifications of fire regimes can be based on the characteristics of the fire itself or on the effects produced by the fire (Agee 1993). Fire regimes have been described by factors such as fire frequency, fire periodicity, fire intensity, size of fire, pattern on the landscape, season of burn, and depth of burn (Kilgore 1987). The detail of a classification determines its best use. The more detailed classifications are primarily useful to ecologists and fire specialists attempting to describe and understand the more intricate aspects of fire. The simpler classifications are more useful for broadscale assessments and for explaining the role of fire to nontechnical audiences.

Heinselman (1978) and Kilgore (1981) produced the first classifications of fire regimes directed at forests. Two factors, fire frequency and intensity, formed the basis for their commonly referenced fire regime classifications (fig.1-1). A difficulty with fire intensity is that a wide range of intensities, including crown fire and surface fire, can cause stand-replacement because mortality to aboveground vegetation is complete or nearly complete. Fire intensity relates only generally to fire severity. Severity of fire reflects (1) the immediate or primary effects of fire that result from intensity of the propagating fire front and (2) heat released during total fuel consumption. Plant mortality and removal of organic matter are the primary fire effects. Kilgore emphasized fire severity in his modification of

Figure 1-1—Comparison of fire regime classifications by Heinselman (1978), Kilgore (1981), Hardy and others (1998), Morgan and others (1998), and the Flora and Fuel Volume. Lines connect similar fire regime types. In parentheses, forest includes woodlands and grassland includes shrublands.

Heinselman's fire regimes by referring to mortality of the primary tree cover as stand-replacement.

Two recent fire regime classifications have proven useful for mapping extensive areas of forest, shrubland, and grassland vegetation at 1 km resolution. Morgan and others (1998) mapped historical and current fire regimes in the Interior Columbia River Basin based on four fire severity and five fire frequency classes (fig. 1-1). Hardy and others (1998) mapped fire regimes of the Western United States using fire severity and fire frequency combined into five classes. They keyed the fire regime classes to spectral images and biophysical data including elevation, hydrologic units, Kuchler's vegetation types, and Bailey's (1995) sections. Results were used to prioritize allocation of funds and resources as part of a national strategy for prescribed fire. For example, high priority for restoration using prescribed fire was assigned to areas where current and historical fire regimes have departed significantly such as in the ponderosa pine type.

Readers who wish to view a more complex ecological classification are referred to the detailed classification of fire regimes developed by Frost (1998). It incorporates periodicity of the fire cycle, primary season of burn, fire frequency, and fire effects on vegetation. It

is very sensitive to fire frequency and its effects on understory herbaceous species. Sensitivity to frequency is provided by recognizing four frequency classes between 0 and 25 years. This separates some eastern and western vegetation into different fire regime types.

The fire regime classification employed in this volume is based on fire severity. Characteristic fire frequencies are reported but not combined with fire severity into classes. Use of fire severity as the key component for describing fire regimes is appealing because it relates directly to the effects of disturbance, especially on survival and structure of the dominant vegetation. It is intended for broadscale applications and for communication about fire's role among resource managers and others interested in natural resources.

Detailed information available about past fire regimes is based mostly on biophysical evidence, written records, and oral reports that encompass the period from about 1500 to late 1800, a time before extensive settlement by European-Americans in many parts of North America, before intense conversion of wildlands for agricultural and other purposes, and before fire suppression effectively reduced fire frequency in many areas. In this volume, we refer to the fire regimes of the

past several centuries as “presettlement” fire regimes. The following describes the fire regime types used in the Flora and Fuel Volume:

1. *Understory fire regime* (applies to forests and woodlands)—Fires are generally nonlethal to the dominant vegetation and do not substantially change the structure of the dominant vegetation. Approximately 80 percent or more of the aboveground dominant vegetation survives fires.
2. *Stand-replacement fire regime* (applies to forests, woodlands, shrublands, and grasslands)—Fires kill aboveground parts of the dominant vegetation, changing the aboveground structure substantially. Approximately 80 percent or more of the aboveground dominant vegetation is either consumed or dies as a result of fires.
3. *Mixed severity fire regime* (applies to forests and woodlands)—Severity of fire either causes selective mortality in dominant vegetation, depending on different tree species’ susceptibility to fire, or varies between understory and stand-replacement.
4. *Nonfire regime*—Little or no occurrence of natural fire.

In this volume, we consider all ecosystem types other than forest and woodland to have stand-replacement fire regimes because most fires in those ecosystem types either kill or remove most of the aboveground dominant vegetation, altering the aboveground structure substantially. Most belowground plant parts survive, allowing species that sprout to recover rapidly. This is true of tundra, grasslands, and many shrubland ecosystems. Morgan and others (1998) consider grasslands to have “nonlethal” fire regimes based on the criterion that structure and composition of vegetation is similar to the preburn condition within 3 years after a burn (fig. 1-1). Because fire radically alters the structure of the dominant vegetation for at least a short time, however, we consider grassland ecosystems to have stand-replacement fire regimes. Because grassland, tundra, and many shrublands are stand-replacement fire regime types, a more interesting aspect of fire regimes in these ecosystems is fire frequency, which can vary substantially and have a major influence on vegetation composition and structure.

The understory and mixed severity fire regimes apply only to forest and woodland vegetation types. The mixed severity fire regime can arise in three ways:

- Many trees are killed by mostly surface fire but many survive, usually of fire resistant species and relatively large size. This type of fire regime was described as the “moderate severity” regime by Agee (1993) and Heyerdal (1997).
- Severity within individual fires varies between understory burning and stand-replacement, which

creates a fine-grained pattern of young and older trees. This kind of fire regime has not been recognized in previous classifications. It probably occurs because of fluctuations in weather during fires, diurnal changes in burning conditions, and variation in topography, fuels, and stand structure within burns (see chapters 5 and 6). Highly dissected terrain is conducive to this fire regime. In actuality, a blend of these two mixed severity types probably occurs.

- Fire severity varies over time with individual fires alternating between understory burns and stand-replacement. Kilgore (1987) described this as the “variable” regime and applied it to redwood forests. It also fits red pine forests (chapter 3).

The fire regime types were simplified from the classifications reported by Heinselman (1978) and Kilgore (1981). They are identical to the fire severity component utilized by Hardy and others (1998) except we use “understory” instead of “nonlethal” to depict that fire regime. We chose the term understory as a fire regime name because the term nonlethal is more easily misinterpreted when considering forest and nonforest ecosystems. Our fire regime classification is similar to that reported by Morgan and others (1998). To show how all of these classifications are related, equivalent or similar fire regime types are connected by lines in figure 1-1. The primary ecological knowledge imparted by fire regime types is whether fires leave the dominant aboveground vegetation standing and alive or result in stand-replacement. To reflect this, the fire regime types used in this volume, are characterized as nonlethal understory fire, stand-replacement fire, and mixed severity fire.

Fire severity is defined by what happens on areas that actually burned. In reality, unburned islands and patches of variable size and shape occur within the perimeter of fires. In studies of historical fire, it is difficult to separate burned from unburned patches. Thus, in applying the classifications, some nonlethal effects of fire can be attributed to unburned patches.

Forests of all types can be grouped into the understory, mixed, or stand-replacement fire regimes, which correspond to low, moderate, and high fire severity types described by Agee (1993). Some forest types occurring over a wide range of environmental conditions can fall into two fire regime classes. For example, most lodgepole pine and jack pine forests were characterized by stand-replacement fire. But some of the forests, typically on drier sites, reflect a mixed fire regime history. Evidence (Arno and others [in press]; Frost 1998) indicates that the mixed fire regime type was more prevalent than previously thought especially in coniferous forests. As fire moves across the landscape its behavior and effects can change dramatically due to variability in stand structure, fuels,

topography, and changing weather elements. This can result in highly variable tree mortality and survival patterns within a fire's boundary. Generally, the severity and intensity of fire are inversely related to fire frequency (Swetnam 1993). For example, stand-replacement fires tend to occur in forests with low frequency, and understory to mixed severity fires tend to occur in forests with high fire frequency. Considerable variability exists within this generalization.

In this volume we consider grasslands and tundra fire regimes to be essentially all stand-replacement because the aboveground dominant vegetation is either killed or removed by fire. Also, many shrubland ecosystems are stand-replacement fire regime types because the dominant shrub layer is usually killed back to growing points in or near the ground. Stand-replacement fire in grass and sedge dominated ecosystems may be either lethal or nonlethal to aboveground vegetation. It is nonlethal if vegetative parts have already cured and exist as dead fuel, which is often the case in Western United States. But it is lethal if some of the aboveground grasses and sedges are living and are killed by fire as is commonly the case in marshes of eastern North America and in tundra. Fire is usually nonlethal to belowground plant parts allowing species that sprout to recover rapidly.

The natural role of fire can be understood and communicated through the concept of fire regimes. Significant changes in the role of fire due to management actions or possible shifts in climate can be readily described by shifts in fire regimes. It is increasingly recognized that knowledge of fire regimes is critical to understanding and managing ecosystems. To assist in this, fire regime types are identified for the major vegetation types in the United States and Canada (tables 3-1, 4-1, 5-1, 6-1, 7-1). The prevalence of each fire regime type within an ecosystem is characterized

as being of major or minor importance. Fire frequency classes defined by Hardy and others (1998) are also tabulated along with a range in fire frequencies where there was sufficient knowledge.

To illustrate the extent and juxtaposition of various fire regimes across the landscape, presettlement fire regime types showing fire severity and fire return intervals were mapped for the lower United States (fig. 1-2). The mapping was based on a digitized atlas of Kuchler's Potential Natural Vegetation Types (Hardy and others 1998) and the fire regime types ascribed to the Kuchler types in chapters 3 to 7. In interpreting the map, keep in mind that Kuchler types represent broad classes; vegetative cover types and fire regime types can vary within the Kuchler types. In the figure legend, the overlapping of fire frequency classes such as 0 to 10 and 0 to 35 years means that the broader class encompasses more variability in fire return intervals and uncertainty of estimation.

The map illustrates the great expanse occupied by the short return-interval, understory fire regime type in the Eastern United States. It is important to note that much of the presettlement oak-hickory type was a savanna classified as forest having an understory fire regime, but it reasonably could have been classified as prairie having a short return-interval, stand-replacement fire regime. The pattern and frequency of the mixed fire regime type varies substantially between western conifers and eastern hardwoods. Although the mixed regime mortality is similar, the fire behavior and species fire resistance differ. Fires in conifers typically are more intense than in hardwoods, but conifers have a higher resistance to fire injury. Mapping of fire regime types and changes between current and historical periods can be useful for broad-scale fire management planning and for communicating with non fire managers about landscape fire ecology.

Figure 1-2—Fire regime types based on Kuchler's Potential Natural Vegetation types (prepared by Jim Menakis).

Chapter 2: Fire Autecology

Fire is a key ecological process within most ecosystems in the United States and Canada. An understanding of factors controlling the initial response of vegetation to fire is essential to its management. Fire effects on plants can vary significantly among fires and on different areas of the same fire. Fire behavior, fire duration, the pattern of fuel consumption, and the amount of subsurface heating all influence injury and mortality of plants, and their subsequent recovery. Postfire responses also depend upon the characteristics of the plant species on the site, their susceptibility to fire, and the means by which they recover after fire.

This chapter describes the key elements that explain fire effects on vascular plants, those plants with specific structures for gathering and transporting water and nutrients. Effects on mosses, lichens, liverworts, algae, and fungi are not discussed. The chapter addresses plant survival, resprouting, and seedling establishment in the initial stages of postfire recovery. Factors that affect a species presence or absence in the immediate postfire community will be described, but not those that affect productivity, such as changes in soil nutrient availability. The adaptations that allow survival, and the methods by which plants recover, are common to species found in almost all of the ecosystems discussed in this volume. The chapter describes principles in a general way, and provides specific examples from different ecosystems, although no

attempt has been made to present examples from every system. Mechanisms operate in the same way no matter where they occur.

Plant Mortality

The likelihood of plant tissue being killed by fire depends upon the amount of heat it receives. The heat received by a plant is determined by the temperature reached and the duration of exposure. Most plant cells die if heated to temperatures between about 122 to 131 °F (50 to 55 °C) (Wright and Bailey 1982). Plant tissue withstands heat in a time-temperature dependent manner. Mortality can occur at high temperatures after a short period (Martin 1963), while death at lower temperatures requires a longer exposure (Ursic 1961). Additionally, some plant tissues, particularly growing points (meristems or buds) tend to be much more sensitive to heat when they are actively growing and their tissue moisture is high, than when their moisture content is low (Wright and Bailey 1982). The concentration of other compounds that vary seasonally such as salts, sugars, and lignins may also be related to heat tolerance of plants. Plant mortality depends on the amount of meristematic tissues killed. Susceptible tissue may not be exposed to heating by fire because it is protected by structures such as bark or bud scales, or is buried in duff or soil.

Plant mortality is often the result of injury to several different parts of the plant, such as crown damage coupled with high cambial mortality. Death may not occur for several years and is often associated with the secondary agents of disease, fungus, or insects. The resistance of plants to these agents is often lowered by injury, and wound sites provide an entry point for pathogens in conifers (Littke and Gara 1986) and hardwoods (Loomis 1973). A plant weakened by drought, either before a fire or after wounding, is also more likely to die.

Aerial Crown Mortality

A woody plant's structure affects the probability that the aboveground portion will be killed by fire. Important aerial crown characteristics include branch density, ratio of live to dead crown material, location of the base of the crown with respect to surface fuels, and total crown size (Brown and Davis 1973). Height enhances survival, as the aerial portions of small stature plants are almost always killed. Species of trees that self-prune their dead lower branches, such as red pine, are less likely to have a fire carry into their crowns (Keeley and Zedler 1998). Small buds are more susceptible to lethal heating than large buds because of their small mass (Byram 1948; Wagener 1961). Large buds, such as on some of the pines, are more heat resistant. The small diameter twigs and small buds of most shrub species make them fairly susceptible to fire. For conifers, long needles provide more initial protection to buds than short needles that leave the bud directly exposed to heat from the fire (Wagener 1961). Whether leaves are deciduous or evergreen affects crown survival in that deciduous trees are much less susceptible during the dormant than growing season.

In order for the aerial crown to survive fire, some buds and branch cambium must survive. For conifers with short needles and trees and shrubs with small buds, crown scorch is often equivalent to crown death because small buds and twigs do not survive (Wade 1986). The upper portions of the crown may survive on taller trees. Large buds shielded by long needles can survive fires that scorch adjacent foliage (Ryan 1990; Wade 1986). The large shielded buds of ponderosa pine, lodgepole pine, western white pine, and western larch can survive at a 20 percent lower height than that where foliage is killed (Ryan 1990). Crown consumption is a better indicator of crown mortality than scorch for fire-resistant conifers such as longleaf pine, which has long needles, large well protected buds, and thick twigs (Wade 1986). Crown characteristics that affect survival of trees after fire are listed in table 2-1.

The scorching of a tree crown is primarily caused by peak temperature heat fluxes associated with the passage of the flaming fire front (Van Wagner 1973).

Long-term heating caused by burnout of fuel concentrations after the flaming front has passed can also scorch crowns. Whether the heat generated by fire is lethal to foliage also depends on the ambient air temperature (Byram 1958). For example, at a 90 °F air temperature without wind, the height of foliage scorch can be approximately 25 percent higher than it would be at 77 °F, because at higher air temperatures less additional heat is required to raise the foliage temperature to a lethal level (Albini 1976). Scorch is also affected by the degree to which heat is dissipated by wind (Van Wagner 1973). In western conifers, the percent of crown volume with scorched foliage is a better predictor of crown mortality than scorch height because it is a better measure of the amount of remaining live foliage (Peterson 1985). In southern pine species, nearly all trees can survive 100 percent crown scorch except during the fall when survival is about 95 percent (Wade 1985; Weise and others 1990). Heat-caused needle damage is detectable within a few days, sometimes within hours, and becomes more obvious over the next several weeks (Ryan and Wade 2000).

Stem Mortality

In fires where aerial crowns are not burned, trees and shrubs can be killed by girdling, caused by lethal heating of the cambial layer, the active growth layer just beneath the bark. Fire resistance of tree stems is most closely related to bark thickness, which varies with species, tree diameter and age, distance above the ground, site characteristics, and health and vigor of the tree (Gill 1995). Some species with thin bark have a fairly thick collar of bark at the base of the bole (Harmon 1984). The insulating quality of bark is also affected by its structure, composition, density, and moisture content (Hare 1965; Reifsnyder and others 1967), factors that vary among species. For example, among central hardwoods, bark of silver maple has a high specific gravity and thermal conductivity, and can transmit heat to cambial layers in less time than bark with a low specific gravity and conductivity, such as bur oak and eastern cottonwood (Hengst and Dawson 1994). Flame length (Brown and DeByle 1987), flaming residence time (Wade 1986), and stem char height (Regelbrugge and Conard 1993; Regelbrugge and Smith 1994) can be related to the amount of mortality of thin-barked trees. The cambium layer of thin-barked trees such as lodgepole pine and subalpine fir is usually dead beneath any charred bark (Ryan 1982). For Northwestern conifers in natural fuel situations, minimum bark thickness associated with consistent tree survival is about 0.39 inches (1 cm) (Ryan 1990). Wade and Johansen (1986) noted that bark as thin as 0.5 inch (1.25 cm) could protect young loblolly and slash pines during dormant season fires with low fireline

Table 2-1—Tree characteristics important to surviving fire and an overall species resistance to fire rating.^a

^a The ratings of physical attributes are relative among the range of conditions observed for all tree species based on reviews of literature.

^b Sizes are defined as follows: seedlings, <1 inch dbh; saplings, 1 to 4 inch dbh; poles, 5 to 10 inch dbh; mature, >11 inch dbh.

^c Size when medium or high fire resistance is gained.

^d For seedlings (loblolly, longleaf, and shortleaf pines) and saplings (loblolly and shortleaf pines). Shortleaf pine is a fairly strong sprouter; loblolly is weaker, and longleaf is the weakest of the three species (Wade 2000).

Figure 2-1—Scorched boles on surviving ponderosa pine, Selway-Bitterroot Wilderness, Idaho.

intensity. A summary of tree bark characteristics related to fire survival is in table 2-1.

Cambium that grows beneath thick bark layers typically found on mature Douglas-fir, western larch, and ponderosa (fig. 2-1), Jeffrey, longleaf, slash, and loblolly pines is insulated from heat released by the flaming front. However, the cambium can be killed by long-duration heating, such as from burnout of logs and smoldering combustion in deep litter and duff layers (fig. 2-2). Complete basal girdling is generally only caused by smoldering ground fires because the amount and distribution of dead woody fuels is rarely adequate to lethally heat the entire circumference of a thick-barked tree (Ryan and Reinhardt 1988). The deeper the basal mound of dry duff that is consumed, the more likely that tree cambium is killed (Harrington and Sackett 1992; Ryan and Frandsen 1991). In thick-barked trees, crown injury is more often the cause of mortality than bole damage (Ryan and Reinhardt 1988).

Fire scars occur where the cambium is killed and often are not evident until the dead bark sloughs from the tree (Smith and Sutherland 1999). Because charring doesn't happen unless the bark actually burns, charring often doesn't occur until a subsequent fire burns the exposed surface. Once tree cambium is injured by fire or mechanical damage, it is often more susceptible to additional fire scarring, both because the bark is thinner near the scar, and because of pitch that is often associated with wounds. Fire scars can become infected by wood-inhabiting microorganisms including decay fungi. The survival of chestnut and

Figure 2-2—Smoldering and glowing combustion in duff can lethally heat tree boles and roots such as in this Douglas-fir/western larch stand, Lubrecht Experimental Forest, Montana.

black oaks after surface fires in Eastern hardwood forests has been attributed to their ability to rapidly and effectively compartmentalize the wound, forming a boundary around the injured and decayed tissue that reduces the spread of infection (Smith and Sutherland 1999).

Many large hardwoods survive fire but have charred bark on the lee side, which in thin-barked species is a telltale sign that the underlying cambium has been killed. Even though the bark often remains intact for 1 or 2 years, the damaged sapwood begins to decay, reaching the heartwood in several years and then progressing upward at a more rapid rate. Height of decay is directly correlated to age of wound (Kaufert 1933). On fast-growing bottomland hardwoods, wounds less than 2 inches (5 cm) wide usually heal over before rot enters, but larger wounds are nearly always infected, ruining the butt log (Toole 1959). Decayed sapwood disintegrates rather quickly, creating the hollow found on many old growth hardwoods in the South. Most hollow trees also develop an enlarged buttress. Toole (1959) found that bottomland hardwoods that initially survive fire suffer considerable mortality over the next several years from breakage of decay weakened stems. Loomis (1973) presented methodology for predicting basal wound size and mortality to surviving trees in oak-hickory stands.

Root Mortality

Structural support roots growing laterally near the surface are more susceptible to fire damage than those growing farther beneath the surface. Roots found in organic layers are more likely to be consumed or lethally heated than those located in mineral soil layers. The locations of structural roots are summarized for important tree species in table 2-1.

Feeder roots collect most of a tree's water and nutrients, are small in diameter, and are usually distributed near the surface. Feeder roots located in organic soil layers are more subject to lethal heating and consumption than those located in mineral soil. Loss of feeder roots may be a more significant cause of tree mortality than structural root damage (Wade 1993). Feeder root death may not always kill the tree, but it can place the tree under significant stress. Increased amounts of root damage can result from fires that smolder in accumulations of litter beneath trees (Herman 1954; Sweezy and Agee 1991; Wade and Johansen 1986). This can be a critically important factor if most of the feeder roots are located in thick duff layers, caused by the exclusion of fire or a regime of dormant season prescribed burning that consumed hardly any surface organic matter. There may be enough root injury or death to kill trees and shrubs,

even though little or no damage is apparent to their aerial crowns (Geiszler and others 1984). While tree crown mortality can be related to fireline intensity, mortality of buried plant parts depends much more on the duration of all phases of combustion that regulates the downward heat pulse, than on the duration of the flaming front (Wade 1986).

Fire Resistance

Tree resistance to fire generally increases with age. Crowns become larger and for some species, the height to the base of the live crown increases, either from self pruning or removal of basal branches by surface fires. Bark thickness and stem diameter increase. A suppressed tree may develop fire resistance characteristics at a much slower rate than a vigorous tree of the same age and species resulting, for example, in a much thinner bark in suppressed loblolly pine (Wade 1993). The growth stage at which important species of trees become fire resistant and the degree of resistance of mature trees are summarized in table 2-1.

Vegetative Regeneration

Sprouting is a means by which many plants recover after fire. Shoots can originate from dormant buds located on plant parts above the ground surface or from various levels within the litter, duff, and mineral soil layers (fig. 2-3). The type of plant parts that support dormant buds and where they are located in or above the soil are species-specific characteristics (Flinn and Wein 1977). The plant structures that give rise to regenerating shoots are summarized for different life forms of North American native plants in table 2-2.

Figure 2-3—Various plant parts that regenerate new shoots and their location in and above the soil.

Table 2-2—Type and location of buds that regenerate new shoots after fire by broad plant groups (X = common, u = uncommon).

Bud type	Location	Trees			Shrubs	Herbs

Stolon	Above soil & duff					X	X
Root collar	In & above soil	u	X	X	X		
Root crown	In & above soil	u	X	X	X		X
Caudex	In soil or duff ^a					X	
Root	In soil or duff ^a		X	X	X		X
Rhizome	In soil or duff ^a				X	X	X
Bulb, corm	In soil					X	

^a Budding organs may grow into duff after it accumulates to suitable depth.

Sprouting of Woody Plants

Dormant Bud Locations—Many woody plant species have dormant buds located in the tissue of stems, above or below the surface of the ground. These plants sometimes sprout from the root collar, the point where roots spread out from the base of the stem. Such species include antelope bitterbrush, bigleaf maple, rabbitbrush, mountain mahogany, turkey oak, northern red oak, and paper birch (table 2-1, fig. 2-4). Epicormic sprouts develop in species such as eucalyptus, pond pine, and pitch pine from buds buried in woody tissue of tree stems, or from bud masses present in branch axils. Lignotubers, burls, and root crowns are names for masses of woody tissue from which roots and stems originate, and that are often covered with dormant buds (James 1984). These buds may be deeply buried in wood, and may be located far below the surface if the tissue mass is large. Plants with this commonly occurring structure include white sage (Keeley 1998), chamise, willow, serviceberry, alder, and tanoak.

An unusual trait shared by pitch, pond, and short-leaf pines is the formation of a basal crook that enhances the ability of these species to produce basal sprouts when the stems are topkilled by fire. When seedlings are small, they fall over (presumably from their own weight), grow prostrate, and then resume vertical growth, which results in a basal crook at the soil surface (Little and Somes 1956). Primary needles with their axillary buds form just above the hypocotyl and just below the second bend of the crook (Stone and Stone 1954; Walker and Wiant 1966). Rootlets also form from the uppermost root tissue close to the bud cluster anchoring the stem in place. Buds on the lower side of the crook are thus well protected from fire. If fire topkills a seedling or sapling, these dormant buds sprout and the same growing process is repeated. Because sprouts originating after the second or third

Figure 2-4—Sprouts of paper birch that developed from root collar, Frenchman Lake, Alberta.

fire have a well-developed root system, their height growth is more rapid than that of the original seedling.

Dormant buds are often located on laterally growing stems or roots of woody plants. Some woody species, such as aspen and horsebrush, have dormant buds or bud primordia located along roots from which new shoots can originate. Rhizomes are the horizontal underground stems that have a regular network of dormant buds that can produce new shoots and adventitious roots (Welsh and others 1987; Zasada and others 1994). Woody rhizomatous species include blue huckleberry, bog blueberry, thimbleberry, white spirea, Gambel oak, creeping barberry, chokecherry, and Labrador tea (fig. 2-5).

Sprouting Process—Postfire sprouting in woody plants is a process that is regulated by the same factors that control vegetative regeneration after other types of disturbances. Consider the physiological interactions that produce new aspen shoots, a model summarized by Schier and others (1985) that likely applies to other plants with buried regenerating structures. The growth of most dormant buds or bud primordia is controlled by a phenomenon called apical dominance. Growth hormones, particularly auxin, a plant hormone manufactured in actively growing stem tips and adjacent young leaves, are translocated to dormant buds, which prevent them from developing into new shoots. If stem tips and leaves are removed, the source of growth hormones is eliminated. The balance of plant hormones within the buds changes. Growth substances in roots, particularly cytokinins, are translocated upward to the buds and can cause the dormant buds to sprout, or stimulate bud primordia to

differentiate into shoots. Cytokinins may already be present in buds, and a decrease in the ratio of auxins to cytokinins provides the stimulus for bud outgrowth.

Fire initiates regeneration from buds by killing surface plant parts that inhibited their growth. The buds that become shoots are usually those nearest to the part of the plant killed by the fire. If dormant buds are destroyed, new buds may differentiate from wound tissue, called callus, and subsequently produce shoots (Blaisdell and Mueggler 1956). Once new shoots are actively growing, they produce growth hormones that are translocated to other dormant buds that are farther away from the point of damage, suppressing their growth (Schier 1972) (fig. 2-6).

The reduced understory cover and thickness of organic layers following fire can increase light near the surface, and in turn promote an increase in sprouting because light can cause rhizome tips to turn upward and develop leafy shoots once they reach the surface (Barker and Collins 1963; Trevett 1956). This possibility suggests that some postfire shoots may develop from rhizome tips, not dormant buds. Schier (1983) found that decapitating a rhizomatous plant caused laterally growing rhizomes to turn upward and become shoots. Additional rhizomes often form in response to vigorous aerial plant growth (Kender 1967), and may subsequently produce aboveground shoots (fig. 2-7). Sprouts from new rhizomes may recolonize areas where old rhizomes and other reproductive plant parts were killed by a fire. Plants may sprout soon after a fire, or not until the following spring if the fire occurs after the plants have become dormant (Miller 1978; Trevett 1962). Warmer soil temperatures following fire may enhance the amount of sprouting that

Figure 2-5—New shoot growth from a rhizome of Labrador tea, Seward Peninsula, Alaska.

Figure 2-6—Suppression of bud outgrowth farther down the stem by actively growing new shoot of blue huckleberry, Lubrecht Experimental Forest, Montana.

occurs (Zasada and Schier 1973). The initial energy required to support growth until the sprout is photosynthetically self-sufficient comes from carbohydrates and nutrients stored in the regenerating structures or in adjacent roots (James 1984).

Postfire sprouting ability can vary with plant age. Young plants that have developed from seed may not be able to sprout until they reach a certain age, which varies by species (Smith and others 1975; Tappeiner and others 1984). Older plants of some species may be able to produce few, if any, sprouts that survive. Older plants (80+ years) of other species such as pitch pine (Little and Somes 1956) can produce stump sprouts prolifically. Minimal postfire root sprouting such as documented in deteriorating aspen stands may be caused by a combination of root system dieback and continued inhibition of sprouting by residual stems (Schier 1975). The ability of selected tree species to vegetatively regenerate after a fire, and the structure

from which the sprouts develop are summarized in table 2-1.

Sprouting and Burn Severity—Burn severity (also called depth of burn and ground char, see glossary) is a measure of the amount of fuel consumption and associated heating at and below the ground surface (also see fire severity in glossary). It is a function of the duration of the fire, and relates closely to the amount of surface fuel, litter and duff consumption, and their moisture content. Severity classes have been defined by Viereck and others (1979) and Ryan and Noste (1985). A strong relationship exists between subsurface heating and postfire sprouting in forested areas (Dyrness and Norum 1983; Miller 1977; Morgan and Neuenschwander 1988; Ryan and Noste 1985), and in rangeland shrubs (Zschaechner 1985), which can be related to the distribution of buried buds (Gill 1995). Figure 2-8 depicts the relationship between the

Figure 2-7—New rhizomes formed on postfire aster sprout that may colonize adjacent areas, East Kootenay Mountains, British Columbia.

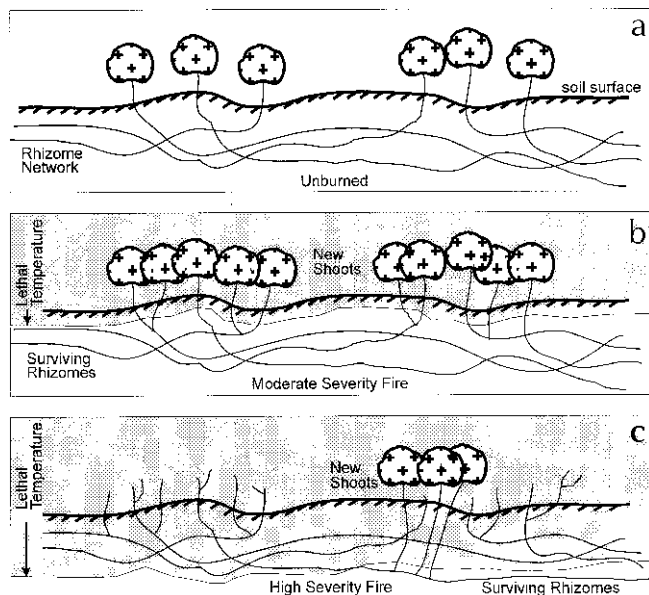

Figure 2-8—Effects of subsurface heating on postfire sprouting of a rhizomatous shrub: (a) Network of unburned rhizomes. (b) Moderate severity fire lethally heated the rhizomes near the surface, but many postfire sprouts grew from more deeply buried rhizomes. (c) High severity fire killed most of the rhizomes, but a few sprouts grew from a deep, surviving rhizome.

amount of postfire sprouting of a rhizomatous shrub and the depth of lethal heat penetration.

A low severity fire (lightly burned, short duration, low ground char) that only consumes some of the surface fuels may kill laterally growing rhizomes or roots near the surface, or stem buds that are not well protected. It has little effect on most buried plant parts and can stimulate significant amounts of postfire sprouting.

A moderate severity fire (moderately burned, moderate duration, moderate ground char) consumes the litter layer, and partially consumes both large woody debris and the duff layer. It incinerates plant structures in litter and the upper duff layer, such as shallow rhizomes, and may kill buds on portions of upright stems that are beneath the surface, and buds on the upper part of root crowns (fig. 2-9). Sprouting occurs from buds in deeper duff or soil layers. Johnston and Woodard (1985) found that mortality of rhizomes of beaked hazel and red raspberry only occurred in areas of relatively high surface fuel loading, but sprouting still occurred from more deeply buried rhizomes that survived the fire. Moderate severity fires frequently cause the greatest increase in stem numbers (fig. 2-8) of root sprouters such as aspen (Brown and Simmerman 1986) and of rhizomatous shrubs (Miller 1976). When heat prunes rhizomes below the surface where rhizome density is high (fig. 2-8b), shoots develop from

buds along the rhizome, and appear as separate plants above the surface. Several shoots can replace what was previously one shoot. Other new shoots may develop from rhizome tips that are stimulated to turn to the surface and become shoots.

A high severity fire (heavily burned, long duration, deep ground char) removes the duff layer and most of the large woody debris, particularly rotten material. It can eliminate species with regenerative structures in the duff layer, or at the duff-mineral soil interface, and may lethally heat some plant parts in upper soil layers, particularly where concentrations of heavy fuels or thick duff layers are consumed. Any resprouting that does occur on heavily burned microsites can only occur from stolons and rhizomes that recolonize from adjacent areas or from deeply buried plant parts (fig. 2-8c). Miller (1977) observed that sprouting was delayed on a severely burned microsite, with a single huckleberry sprout not emerging until the third growing season from a rhizome about 9 inches below the surface. Abundant vegetative regeneration can still develop from species with deep roots such as aspen, or deep rhizomes such as Gambel oak.

Sprouting of Forbs

In North America north of the tropics, perennial forbs are broad leaved species that completely regrow their leaves and stems each year, after dying back during winter cold or summer drought. Some of these plants can persist in closed canopy environments that develop in the years after fire, producing a few leaves at the beginning of each growing season, which are often eaten by animals, or die back as the soils dry out (Christensen and Muller 1975).

Forbs have regenerative structures that are similar to those in woody plants, but also some that are unique. Stolons are stems of herbaceous species that grow on or near the surface of the ground, producing plants with roots at the node apex such as a series of strawberry plants (Benson 1957; Welsh and others 1987), and twinflower (McLean 1969). Dormant buds of fireweed and bracken fern are located on roots. Western yarrow, heartleaf arnica, showy aster, wild sasparilla, and star-flowered Solomon's seal are rhizomatous forb species.

A caudex is a largely underground, often woody stem base that persists from year to year and produces leaves and flowering stems (Benson 1957; Welsh and others 1987). This structure is found in species such as Indian paintbrush, lupine, wild columbine, and arrowleaf balsamroot. Other buried reproductive structures include bulbs (buried buds covered with thick fleshy leaves) found in common camas and deathcamas and corms (bulb-like, short thickened stems) of glacier lily and gayfeather species.

Figure 2-9—Sprouts originating from root crown of serviceberry, after a moderate severity fire killed buds on uppermost exposed surfaces, Piceance Basin, northwestern Colorado.

Leaves and stems suppress outgrowth of subsurface dormant buds. If fire occurs during the growing season, death of the apical meristems removes inhibition of subsurface buds and new shoots form. If a fire occurs when herbaceous plants are seasonally dormant, fire does not remove the source of inhibition because aboveground leaves and stems are cured and sometimes already decomposed. Dormant structures will grow new leaves after the occurrence of appropriate seasonal cues of temperature and moisture. Whether herbaceous plants recover after fire depends largely on whether their regenerative structures are exposed to lethal temperatures. Similar to woody plants, their survival depends on depth below the surface, whether they are located in combustible material, and the subsurface moisture regime at the time of the fire. While the stolons of strawberries make them susceptible to even low severity fire, the deep rhizomes of showy aster allow survival of some plants after fairly severe fires. Lupine and timber milkvetch can regenerate even when the entire plant crown is consumed (McLean 1969). Fireweed and bracken fern can produce

significant numbers of sprouts after high severity fires because many buds far below the surface can survive even severe fire treatments (Frye 1934; Moss 1936). In California, 57 of 58 herbaceous perennial species resprouted after wildfire in chaparral (Keeley 1998).

Sprouting of Grasses

New leaf tissue of grasses forms at the meristems during the active growing period, and resumes after summer quiescence or winter dormancy. New growth also may occur by “tillering,” branching from dormant axillary buds in the plant crown or on rhizomes. Grass plants are killed when all meristems and buds are lethally heated. Cool-season grasses that green up early in the growing season can be killed by the burning litter of associated warm-season grasses that are still dormant and more heat resistant (Anderson 1973). Perennial grasses also may be killed if fire burns in the cured litter of annual grasses while perennials are still actively growing (Wright and Klemmedson 1965).

Stoloniferous and Rhizomatous Grasses—

Stoloniferous grasses are frequently killed by fire because most stolons are at or near the surface. Whether rhizomatous grasses are stimulated or killed by fire depends on rhizome depth below the surface, whether rhizomes are located in mineral or organic soil layers, the moisture content of these layers, and the amount and duration of heat generated by the surface fire. Rhizomatous grasses such as western wheatgrass often respond positively to rangeland fires because meristems and buds are usually protected by soil, and a long duration source of surface heat over large, contiguous areas is rarely present (Wright and Bailey 1982). In forested areas, grass rhizomes are more likely to be located in litter or duff layers or in association with dead woody fuels. On sites where fire consumes the duff layer, grass rhizomes located in the duff, such as pinegrass may be killed (S. A. Snyder 1991). However, some rhizomes often survive in deep mineral soil layers and can rapidly re-colonize severely burned areas.

Bunchgrasses—Meristems and dormant buds of different bunchgrass species can be located within the bunch above the level of the soil, or at various depths below the soil surface. Buds and meristems can be readily exposed to lethal temperatures, or be fairly well protected if deeply buried in unburned organic materials or in soil. For example, buds in the fairly compact root crown of Idaho fescue lie at or above the surface of the ground and are easily killed (Conrad and Poulton 1966), while basal meristems of bottlebrush squirreltail, Thurber's needlegrass (Wright and Klemmedson 1965), and wiregrass lie about 1.5 inches (4 cm) below the mineral soil surface and are more fire resistant (Uchytel 1992) (figs. 2-10, 2-11).

The moisture content of bunchgrass plants and adjacent fuels affect the amount of heat that the meristems receive. If plants are actively growing, their foliar moisture content can be too high to allow fire to enter the stand of plants. If bunchgrass crowns are moist, it is unlikely that they will ignite and burn. If the dead center of a bunchgrass plant is dry, it can ignite, smolder, and burn, killing most or all growing points. Heat from burning shrubs can dry and preheat adjacent bunchgrass clumps to ignition temperature, causing higher bunchgrass mortality than on a similar site with few shrubs that burned under the same conditions (Zschaechner 1985).

Dry bunchgrass crowns that are ignited are not always consumed. Midsummer fires in northwest Colorado burning under high windspeeds charred only the tops of the crowns of bluebunch wheatgrass and Indian ricegrass plants that were 4 to 5 inches (10 to 13 cm) in diameter. In this case, despite dry conditions, fire may have moved through the grass litter too quickly to

ignite the root crowns, resulting in little plant mortality (Petersburg 1989).

Wright (1971) discussed the relationship between stem coarseness and the rate at which a bunchgrass clump burns. Fire tends to pass fairly quickly through coarse-stemmed bunchgrasses, which do not have much fuel concentrated at their base near reproductive structures. Fine-stemmed grasses with a dense clumping of basal stems can burn slowly and generate a fair amount of heat that can be transferred to meristems and buds. Fires tend to burn more rapidly through small-diameter bunches compared to large-diameter bunches. Larger bunches usually have more dead fuel and are thus more likely to produce enough heat to kill growing points (Wright and Klemmedson 1965). These relationships support Petersburg's (1989) observation that high rate of fire spread may have contributed to the survival of moderate diameter bunches of fine textured grass in northwestern Colorado that otherwise may have suffered fairly high mortality.

A rangeland bunchgrass grows where little surface fine fuel surrounds the plants, other than the dead grass blades immediately associated with the grass crown. The amount of postfire sprouting in this environment can be related to the amount of growing point mortality (Conrad and Poulton 1966). For those species having meristems above the mineral soil surface, the highest postfire sprouting potential usually is found in those plants with only some surface litter removed. Sprouting decreases as the amount of basal litter consumption increases, with new shoots tending to appear only from the outside edge of the bunch when little unburned stubble remains. Mortality is most likely to occur if all plant material above the root crowns is consumed.

Seedling Establishment

Seedling establishment is affected by the amount of seed present and conditions required to induce germination and provide a favorable environment for initial seedling growth. The interaction between the seed and its environment determines whether it successfully germinates and establishes. Requirements for successful germination and establishment can differ significantly among species.

Seed Supply and Dispersal

The supply of seeds of a given species is greatly influenced by annual seed production, which can vary significantly (Zasada and others 1978). Conifer regeneration may be limited if cone crops are poor during the time when exposed mineral soil seedbed is present. Surviving plants on or near the burned area may be too young (Barney and Frischknecht 1974; Zasada 1971)

Figure 2-10—Sand dropseed producing postfire growth from root crown meristems at the soil surface, Guadalupe Mountains National Park, western Texas

Figure 2-11—Basin wildrye growing after a fire from meristems below the soil surface, Bighorn Mountains, Wyoming.

or too old to produce much viable seed. Species of pines occurring in high fire frequency habitats generally begin producing cones earlier than other pine species (Keeley and Zedler 1998).

The timing of seed dispersal is a species-specific characteristic that varies with elevation and latitude (Zasada 1986). The occurrence of fire with respect to the dispersal of seeds can determine the rapidity of regeneration. Heat from fire may kill seeds that have recently fallen to the ground, preventing establishment of that species until after the next year's seedfall.

Seeds that are available to recolonize a burned site may have originated on-site or been dispersed from off-site after the fire. On-site seeds may come from surviving trees, from plants that grow after the fire, or from seed stored in the soil before the fire. The amount of off-site seed dispersal from unburned areas depends on the amount of available seed, the distance of the seed source from the burned area, the prevailing wind direction, and the type of seed. Seed dispersal mechanisms vary. Light seeds may be carried aloft while heavier seeds may skid across the surface of the snow. Some seeds have wing-like structures that enhance their movement through the air. Seeds with barbs or hooks may be carried in fur or feathers. Hard-coated seeds ingested along with their fruit pass through the bird or animal, sometimes with an enhanced likelihood of germination. Mature capsules of some species explosively release their seed (Parker and Kelly 1989). Animals and birds can disperse seeds at great distances from the parent plant, with Clark's nutcrackers (*Nucifraga columbiana*) observed to carry pinyon pine seed up to about 9 miles (Chambers and others 1999).

After dispersal, many seeds remain on or near the surface, although gravity, freezing and thawing, litterfall, and foraging activities of mammals, birds, and insects can deeply bury seeds (West 1968; Tomback 1986). Clark's nutcrackers, pinyon jays (*Gymnorhinus cyanocephalus*), squirrels, and mice cache a significant proportion of seed of certain species below the surface. There, seeds may exist within a matrix of soil, organic material, or a mixture of both.

Seedbank

The seedbank, the supply of seeds present on a site, is composed of transient and persistent seeds, which may be in litter and soil layers and in the tree canopy (table 2-3). There may be an enormous reserve of seed in the seedbank. Seed supply of various species and inherent seed longevity both affect the numbers of viable seeds. Some plants produce seeds that are a transient part of the seedbank, such as willow, which may remain viable for only a few weeks. There is little or no annual carryover of pine seed in soil seedbanks (Pratt and others 1984), and few conifer seeds are

present in the forest floor of a mature forest (Archibold 1989; Ingersoll and Wilson 1990; Kramer and Johnson 1987). Many seeds, particularly large ones, are lost from the seedbank by predation.

Soil-Stored Seed—In a ponderosa pine community, viable seeds of most grass and annual forb species were found mostly in the litter layer, indicating short longevity or recent dispersal, while seeds of perennial forb species were found mostly in mineral soil, and probably were fairly long-lived (Pratt and others 1984). Seeds of some species persist in the soil for years after dispersal. Seeds of pincherry can survive in the seedbank for up to 100 years after the parent trees have died out of the overstory (Whittle and others 1997), while snowbrush ceanothus seeds remain viable for 200 to 300 years or more (Noste and Bushey 1987).

Species present in the seedbank of mature deciduous (Pickett and McDonnell 1989) and coniferous forests (Archibold 1989) are often shade-intolerant, early seral species, which may not be present in the overstory or understory. Few large seeded or shade tolerant species reside for long in the deciduous forest seedbank (Pickett and McDonnell 1989). In many grassland communities, there is a distinct difference between the species growing on the site and those present in the seedbank (Rice 1989). Seedbanks tend to contain more annual than perennial species, more forbs than grasses, many leguminous species, and more weedy species that colonize disturbed sites. In contrast, the chaparral seedbank generally reflects the composition of the standing vegetation with large, persistent seed banks of many species of dominant shrubs, although significant numbers of "fire-following" annuals may also be present (Parker and Kelly 1989). The life-forms of plants likely to have soil and canopy stored seed are shown in table 2-3.

Canopy-Stored Seed—Serotinous cones of species such as lodgepole, jack, pitch, Table Mountain, and pond pines retain some of their seeds because of the presence of a resin bond between scales on some of their cones. Serotinous cones slowly open and release their seeds after they are heated to at least 113 to 122 °F (45 to 50 °C), a temperature that melts the resin bond (Lotan 1976). Cones protect a significant portion of pitch pine seeds from the high temperatures reached during fire (Fraver 1992). Lodgepole pine seeds survived in cones heated in flames for a length of time typical of crown fires (Despain and others 1996). Numerous viable lodgepole pine seeds are dispersed even after a long duration crown fire. There is considerable variation in the amount of lodgepole cone serotiny, both on individual trees (fig. 2-12), and geographically. A high degree of cone serotiny is likely to occur where there are large, stand-replacement fires; relatively short, fire-free intervals; and fire sizes large

Table 2-3—Occurrence of transient seeds and persistent seeds consisting of soil and canopy stored and fire stimulated seed germination for broad plant species groups in the United States and Canada.

Grasses	X			

enough to limit seed dispersal from unburned areas (Muir and Lotan 1985; Parker and Kelly 1989).

The semiserotinous cones of black spruce open and release their seeds over a period of years (Zasada 1986). Cones are usually bunched near the top of the tree, which shields some cones from heating and provides a postfire seed source. An additional on-site seed source from canopies may be immature cones that survive a fire and continue to ripen. This has been observed in ponderosa pines with scorched foliage (Rietveld 1976), in white spruce with boles completely

girdled by fire (Zasada 1985), and in scorched cones of western larch and Douglas-fir where the tips of the seed wing had been singed (Stickney 1999).

Seed Environment

The seed environment describes the microsite in which a seed rests after it has been dispersed from the parent plant, including seedbed, temperature, humidity, shade, and potential competition from other plants. Moss, litter, and duff are poor seedbeds in many

**Figure 2-12**—Jack pine branch with serotinous and nonserotinous cones. Jack pine is ecologically similar to and hybridizes with lodgepole pine, Acadia National Park, Maine.

climates because they frequently dry out in the summer, resulting in seedling death if roots have not yet reached mineral soil. Organic seedbeds, even rotting logs, may be able to successfully support seedling establishment and survival if water is not limiting during the growing season (Zasada 1971). Other attributes of organic seedbeds such as the presence of allelopathic chemicals may inhibit seedling establishment. Oak litter has been observed to be a mechanical barrier to Table Mountain pine regeneration, although it enhances germination and survival of oak seedlings (Williams and Johnson 1992).

Fire creates significant changes in site conditions, which can vary substantially within the burned area depending on the severity and pattern of the fire. Consumption of fuel, especially the forest floor, is an important determinant of postfire conditions, because it controls the amount and distribution of good seedbed conditions. Where bare mineral soil seedbeds are created, any allelopathic chemicals are volatilized (McPherson and Muller 1969; Everett 1987b). Nutrients may be more readily available in ash, and the mineral soil does not dry out as readily as organic material. Moisture was more readily available at 12 inch depths beneath exposed mineral soil than below organic layers in late summer, allowing better growth of seedlings that can develop taproots such as ponderosa pine (Harrington 1992). The blackened surface causes warmer soil temperatures that enhance nutrient cycling and can favor growth, particularly in cold limited environments such as the boreal forest (Viereck and Schandelmeier 1980). After a severe fire, there is less competition from sprouting plants, seedlings, and trees if feeder roots and seeds stored in the duff and soil were killed. There may be little shade in the first few postfire years because of plant mortality. The length of time that a seed environment retains these characteristics after fire determines the number of postfire years that establishment of certain species from seed can take place (Shearer and Stickney 1991).

The physiological requirements of individual species determine whether postfire conditions are favorable for seedling establishment. For most species that develop from seeds dispersed after fire, the best

seedbeds are microsites where most or all of the organic layer has been removed by fire because they provide the greatest chance for seedling survival. For some shade intolerant species, this is the only time that seedlings can establish, but these conditions can result in abundant regeneration, notably of western larch and many species of pine. Some perennial forbs resprout after fire, flower, and produce abundant seeds that establish in the second and subsequent postfire years (Keeley 1998). Wiregrass produces copious amounts of viable seed only after late spring and early summer burns.

If some residual organic matter remains, species with rapidly elongating roots may be favored over species that grow more slowly. Small seeded species are more likely to establish where little organic matter remains. Because seedlings originating from small seeds may be quite limited in their ability to grow through organic layers to mineral soil (Grime 1979), species with large seeds may be favored over small-seeded species where duff layers still exist.

In an Alaskan black spruce/feathermoss (Schreber's and mountain fern mosses) stand, germination and first year survival of black spruce and seven species of deciduous trees and shrubs occurred on both moderately and severely burned seedbeds. However, by the third year, seedlings survived almost exclusively on severely burned surfaces with no residual organic matter (Zasada and others 1983) (table 2-4).

Some species that establish from seed may be temporarily eliminated from a burned area because the postfire environment does not favor their establishment. In chaparral communities, species such as Nuttall's scrub oak, hollyleaf cherry, and toyon recover by sprouting after fire and thus remain on the site. However, seedlings of these species do not establish until the canopy closes and a deep litter layer forms (Keeley 1992).

Fire Stimulated Germination

Dormant seeds will not germinate when exposed to appropriate temperature and moisture conditions (Keeley 1995). Dormancy is maintained by environmental

Table 2-4—Seedling establishment on moderate and heavily burned seedbeds in an Interior Alaska black spruce forest.

Species	Number of germinants		Number of year 3 survivors	
	Moderately burned	Heavily burned	Moderately burned	Heavily burned
Alder	33	160	0	65
Paper birch	72	875	6	527
Balsam poplar	17	71	0	39
Bebb willow	105	144	0	46

conditions such as high and low temperature, low moisture, and inadequate amounts or quality of light (Baskin and Baskin 1989); or it can be imposed by an impermeable seed coat (Stone and Juhren 1953). Some species, such as chamise and hoaryleaf ceanothus, produce a proportion of seeds that remain dormant, while other seeds from the same plant will germinate under any suitable moisture and temperature conditions (Christensen and Muller 1975).

Fire can induce germination of dormant seeds of some species, resulting in an abundance of seedlings of these species in the first postfire year. Because essentially no seed germination occurs in subsequent years, annual plants flower, set seed, and are gone after the first year. Perennial seedlings that mature will flourish, depending on their inherent longevity, for as long as the site meets their specific environmental requirements. Eventually, they may persist only as seeds.

Germination of hard seeds can occur only after fire ruptures seed coat fissures or causes cracks to form in the seed coat, allowing water to enter (Keeley 1987; Rasmussen and Wright 1988). Requirements for optimum germination may be specific. Redstem ceanothus seed has the highest percentage of germination after exposure to moist heat at 176 °F (80 °C) (Gratkowski 1973), followed by stratification through a period of exposure to cold, wet conditions (Quick 1959). Fire stimulated germination has been documented for other hard-seeded genera including *Cassia*, showy partridgepea (Martin and others 1975; Tesky 1992); *Iliamna*, particularly wild hollyhock (Brown and DeByle 1989); *Lotus* or trefoil species (Keeley 1991); *Rubus* including blackberries and raspberries (Morgan and Neuenschwander 1988; Rowe 1983; Stickney 1986); *Ribes* such as gooseberry and currant (Lyon and Stickney 1976); and *Prunus* (Morgan and Neuenschwander 1988). Plant life-forms with fire-stimulated seed germination are shown in table 2-3.

Dormancy of species without hard seed coats can be broken by exposure to smoke and to chemicals leached from charred materials, although some species will germinate only in association with additional stimuli, such as cold stratification or burial (Keeley and Fotheringham 1998). This phenomenon has been studied most intensely in Mediterranean ecosystems, such as chaparral, and in Australia. Germination of chamise and many herbaceous species of the California chaparral can be induced by these treatments (Keeley 1991). Smoke exposure requirements varied significantly among species, with the duration of exposure that is optimum for germination for some species being lethal to others (Keeley and Fotheringham 1998). This suggests that seed germination in chaparral, both pattern and species, may be relative to different types of fire behavior and levels of fuel consumption, because these can result in significant variation in the amount and

duration of smoke. Fire behavior may also relate to establishment of lodgepole pine. The greatest proportion of germination of lodgepole pine seeds from serotinous cones was enhanced by exposure of cones to a duration of flaming that most commonly occurs in crown fires (Despain and others 1996).

Seed germination for some chaparral species is adapted to wildfires that normally occur during fairly hot, dry late summer or fall conditions. Some seeds require dry heat to induce germination, but are killed by lower temperatures if they have imbibed moisture. Other seeds require higher temperatures for a longer duration to induce germination than generally occur under spring burning conditions (Parker 1989). If chaparral sites are burned under moist spring conditions, germination of both of these types of seeds is often much reduced. This is a particular concern for maintaining seedbanks of fire-following annuals, shrubs, and perennial forbs that can only reproduce from stored seed (Parker 1987a).

Burn Severity and Seed Regeneration

Variation in burn severity including its pattern and associated effects on seed mortality, seed stimulation, and seedbed quality can cause considerable variation in seedling numbers and species after a fire. The influence of burn severity on regeneration depends partly on where seeds are located. Viable seeds are characteristically present at different depths within the duff and soil profile. Seed produced by short-lived species that are stimulated to germinate by the heat of the fire, or that establish only on bare mineral soil, are usually found at the base of the forest floor layer, on top or near the surface of the mineral soil (Stickney 1991). Seeds of longer lived early seral species will be present near the duff mineral soil interface but will also have some vertical distribution within the duff layer. On sites without disturbance, these plants may have died out, and their seeds may not be present in the uppermost layers. Transient seeds are only present on and near the surface of the litter layer.

While fire kills most seeds within the surface litter layer, the temperature and duration of subsurface heating controls the amount of mortality and heat-stimulation of buried seed (Morgan and Neuenschwander 1988; Weatherspoon 1988). The pattern of severity relates to the pattern of fuel consumption and can cause variable mortality or stimulation of seeds around a burned site. Where little soil heating occurs, few heat-requiring seeds may germinate. Redstem ceanothus seedlings tended to occur on severely burned microsites within a matrix of less severely burned sites (Morgan and Neuenschwander 1988). If the lethal temperature isotherm penetrates below the level at which most duff and soil stored seeds occur, much

less postfire plant establishment from the soil seedbank will occur than after a fire of more moderate severity (Weatherspoon 1988). However, there can still be a significant amount of regeneration from seedbank species where seeds in lower layers were heat stimulated but not lethally heated. Generally, the dryer the fuels, the more severe the fire, and the more seedbank mortality will occur. Fires of high burn severity also create more bare mineral soil seedbed, opening the site to colonization by seed dispersed from on-site or off-site after the fire. For those obligate, early seral species that only establish on bare mineral soil seedbeds, fires of high burn severity favor their regeneration.

Seasonal Influences

Carbohydrates

Carbohydrates, primarily starches and sugars, are manufactured by plants and provide energy for metabolism, and structural compounds for growth (Trlica 1977). Energy and material needed for initial plant growth following fire are provided by carbohydrates stored in undamaged plant parts, usually belowground structures. The timing of a fire, and its relationship to a plant's carbohydrate balance, can be a factor in postfire recovery because the rate and amount of regrowth is related to carbohydrate reserves (Trlica 1977).

The importance of carbohydrate reserves to plant regrowth after fire depends on survival of photosynthetically capable material, such as leaf blades and sheath leaves on grass stubble (Richards and Caldwell 1985). If some photosynthetic tissue remains or new tillers rapidly regenerate, newly grown leaf material soon manufactures all the carbohydrates that the plant needs for growth and respiration (Caldwell and others 1981). Evidence from clipping and grazing studies has shown that the recovery of grass plants is more related to the removal of growing points than to the carbohydrate level at the time of defoliation (Caldwell and others 1981; Richards and Caldwell 1985). However, fire may have a greater impact on grass plants than severe defoliation because it kills all photosynthetic material and elevated meristems. New growth must be supported by stored reserves.

There is a seasonal cycle of depletion and restoration of total nonstructural carbohydrates related to the growth cycle of the plant. The most rapid depletion usually occurs during periods of rapid growth, but carbohydrates may also be used for flower and fruit development, cold-acclimation ("hardening off" for winter), respiration and cellular maintenance during winter dormancy, and warm weather quiescence (Trlica 1977). Restoration of carbohydrates occurs when pro-

duction by photosynthesis exceeds demands for growth and respiration. The timing of fluctuations in the annual cycle of total nonstructural carbohydrates (TNC) differs among species because of variability in plant growth cycles and growing season weather (Zasada and others 1994).

The limited survival of chamise sprouts after spring prescribed fires has been attributed to low winter and spring carbohydrate reserves because of high spring demand for growth, flowering, and fruiting (Parker 1987b). Number and dry weight of shoots of salmonberry were lowest on rhizome segments collected from May through July, which was also the seasonally lowest level of stored TNC (Zasada and others 1994). Salmonberry is most susceptible to physical disturbance during this time (Zasada and others 1994). For other species, the effects are most negative if the plant is burned late in the growing season because the plant uses a considerable amount of stored carbohydrates to sprout, but does not have enough time to restore reserves before winter dormancy (Mueggler 1983; Trlica 1977).

Severely burned chamise root crowns produced fewer sprouts than plants that experienced less heating, probably because more dormant buds were killed. Subsequent death of plants and limited sprouting may occur because insufficient carbohydrates are produced to sustain the root mass (Moreno and Oechel 1991). Root system dieback after excessive defoliation (Moser 1977) is considered to be a significant cause of plant mortality in grasses.

Repeated burning during the low point of a plant's carbohydrate cycle can increase any negative effects of treatment. Reduced density, canopy cover, and frequency of Gambel oak in southwestern Colorado, after two summer burns 2 years apart, were attributed to an inability to restore spent carbohydrate reserves for the 9 months after top-killing and resprouting (Harrington 1989). In the Southeast, annual summer burning nearly eliminated understory hardwood vegetation in a loblolly pine stand (Waldrop and Lloyd 1991). Burning when carbohydrates were low eventually killed or weakened root systems. Annual winter burning resulted in significant increases in numbers of small diameter sprouts on these same plots, because burning occurred when reserves were fairly high and sprouts had a full growing season to restore reserves before the next treatment.

If burning occurs in close association with heavy use of the plant community by livestock or wildlife, either before or after the burn, plant recovery may be delayed or prevented because of the excessive demand on stored reserves. Heavy postfire grazing or browsing of perennial plants in the first growing season after a fire is likely to cause the most harm, particularly in arid and semiarid range communities (Trlica 1977).

Flowering

Burning has long been used as a tool to enhance flower and fruit production of blueberry. Flowering of grasses such as pinegrass and wiregrass has been noted to increase significantly after burning (Brown and DeByle 1989; Uchytel 1992) (fig. 2-13). Burning during the growing season of April to mid-August causes profuse flowering of wiregrass in Florida, a marked contrast to a paucity of flowering that follows dormant season burning (Myers 1990b). Warmer soil temperature resulting from litter removal in these months may be the flowering stimulus (Robbins and Myers 1992). Increased light resulting from removal of the chaparral canopy stimulates flowering in golden brodiaea, a perennial forb that produces only vegetative growth in the shade (Stone 1951). This has also been observed in the Northern Rocky Mountains, in heartleaf and broadleaf arnicas, showy aster, and pinegrass. Increased availability of soil moisture and soluble nutrients also stimulates increased flowering.

In response to late spring fires, Henderson and others (1983) observed significantly greater flowering

in big bluestem, little bluestem, sideoats grama, and Indian grass, all Wisconsin warm-season grasses. Increased flowering was attributed to higher levels of carbohydrate production caused by improved growing conditions, such as mulch removal. Grass flowering and seed production draw heavily upon carbohydrate reserves. Higher net photosynthate production was observed in big bluestem after spring burning. In contrast, cool-season grasses that were actively growing during late spring experimental fires showed a marked reduction in flowering, possibly because growth initiated after the fires further depleted carbohydrate reserves already drawn down by early growth. There also may have been more damage to meristematic tissue because plants were actively growing at the time of burning.

Fires enhanced flowering of dominant forb and shrub species in longleaf pine forests on the Florida panhandle (Platt and others 1988), with the most significant effects resulting from growing season fires. These fires increased the number of flowering stems, decreased the average flowering duration per species, and synchronized the period of peak flowering of

Figure 2-13—Abundant flowering of Thurber's needlegrass the first growing season after an October prescribed fire, near Carey, Idaho.

herbaceous plants, particularly fall flowering composites with a clonal growth form. Fire killed the elevated apical meristems, which no longer suppressed dormant buds on rhizomes, roots, and stolons. Multiple stems were initiated from these buds at times of the year when photoperiod strongly induced flowering. Dormant season fires had little effect on flowering periods because apical meristems were located at or below the ground surface, were little affected by fire, and continued to suppress secondary meristems the next growing season.

These mass flowering events are a means by which plants that regenerate after the fire redistribute themselves within the stand (fig. 2-14). For plants that germinate from soil stored seed, their profuse flowering in the first few years after fire resupplies the seedbank and ensures their presence after the next fire (Stickney 1990) (fig. 2-15).

Phenology

Plant growth stage at the time of a fire can result in different plant responses. Fire effects can vary substantially during a specific season, such as spring, because several phenological stages can occur in that 3 months. Phenology and the accompanying variation in plant condition, not season, leads to observed differences in plant response to fire. Phenological differences that

affect plant responses to fire include varying levels of stored plant carbohydrate, presence of elevated herbaceous meristems that are more susceptible to fire because of their location, and presence of actively growing tissues that are more sensitive to high temperatures than when they are dormant or quiescent. The seasonal growth pattern that is characteristic of each species can be significantly modified by temperature and moisture in a specific year.

As an example of seasonal influences, ponderosa pine trees scorched in late October survived higher percentages of crown damage than trees scorched in early June and mid-August. The increased survival of fall burned trees was attributed to reduced physiological activity, lower bud tissue moisture contents, bud protection by fully developed bud scales and needles, and replenished carbohydrate stores, allowing adequate reserves to support spring shoot and root growth (Harrington 1987a, 1993).

Phenology also affects flammability. Moisture content of 1 year and older foliage of Western conifers is lower in the early part of the growing season than later in the summer (Chrosiewicz 1986; Jameson 1966; Philpot and Mutch 1971), and may contribute to higher spring crowning potential (Norum 1975). Seasonal differences in the moisture content of surface vegetation can determine whether the vegetation is a heat sink or is dry enough to be a heat source and thus

Figure 2-14—Postfire seed production by arnica, Bob Marshall Wilderness, Montana.

Figure 2-15—Flowering of wild hollyhock, developed from seeds stimulated to germinate by fire, Caribou National Forest, Idaho.

contribute to fire spread. Seasonal curing of herbaceous vegetation changes it from live to dead fuel.

Burning Conditions

Fuel and soil moisture conditions have a major influence on upward and downward heat flows that affect plant responses. Seasonal fluctuations in temperature and precipitation cause a progression of moisture content in dead woody fuels, litter, duff, soil organic layers, and soil. For a given vegetation and fuel type, burning conditions vary seasonally according to a general pattern; and the response of individual plant species to fires occurring under typical seasonal fuel and soil moisture conditions are fairly predictable based on their life-form.

Yearly variations in weather and associated departures from average moisture conditions can cause substantial variation in fire behavior and fire effects. For example, a winter and spring of above average precipitation results in wet woody fuels and duff in higher elevation forests that limit fire spread and fuel consumption. Below average precipitation in winter and spring can create dry enough conditions in forests to create potential for fires with high fuel consumption, and significant amounts of heat release both above and below the surface. Dry large fuels, duff, and mineral soil increase the potential for significant

amounts of surface and subsurface heating, with concomitant mortality of roots, buried regenerative structures and seeds, and tree cambium.

Differences in seasonal weather in shrub/grass types can result in a large range in grass production, particularly annual species, which creates different fire behavior potentials. A wet year in the Great Basin leads to much more herbaceous biomass in sagebrush/grass communities, a greater likelihood of ignition, and larger sizes of fires that do occur. However, whether these higher fuel loadings relate to greater consumption of basal fuels and higher mortality of bunchgrasses and sprouting shrubs has not been documented.

The pattern of fire effects across the landscape varies with burning conditions. Areas of tree crown consumption, crown scorch, and little crown damage can be intermixed (fig. 2-16). Heavily burned areas of the forest floor where significant amounts of fuel were consumed and most buried plant parts were killed can be adjacent to areas where prefire fuel loading was low, and little subsurface heating occurred (fig. 2-17). On rangelands, the pattern can vary between areas of significant heat release associated with consumption of shrubs and accumulated litter and other areas where little heat was generated due to sparse fine fuels (fig. 2-18).

During a dry season, especially in a drought, a much higher percentage of forest canopy is apt to be scorched

or consumed. Lethal temperatures may be driven to greater depths because fuel and duff consumption is fairly complete. During a wet year or early in the year before significant drying has occurred, less canopy will be killed and consumed and few buried plant parts will be killed.

Discussion

Plant response to fire is a result of the interaction between severity of the fire and characteristics of the plants in the fire, both their inherent resistance to injury and ability to recover. Fuel quantity and arrangement, fuel moisture content, topography, windspeed, and structure of the plant community itself cause the lethal heat zone created by fire to vary significantly in time and space. Fire can cause dramatic and immediate changes in vegetation, eliminating some species or causing others to appear where they were not present before the fire. However, in burned areas with a high component of surviving trees and resprouting understory vegetation, within a few

years it can be difficult to determine that a fire recently occurred.

For the vascular plant groups discussed in this chapter, the recovering plant community, in the first few years after a fire, comprises individuals from the following categories:

- Plants that survived the fire with their form intact
- Sprouts or suckers that grew from the base or buried parts of top-killed plants
- Plants that established from seed

Seedlings can be further described as:

- Plants that re-established from seed dispersed from surviving plants, usually trees
- Plants that re-established from seed dispersed from off of the burned site
- Plants that re-established from fire stimulated seed within the seedbank
- Plants that re-established from seed that developed on plants that resprouted after the fire

Certain species can only recover after fire by a single means. Some will only be present after fire if regenerative structures survive and produce sprouts, because their seedlings are unlikely to survive in postfire environments. Species of plants that cannot resprout after top-killing must establish from seed. However, some species can successfully recover from fire both by resprouting and by seedling establishment. Severity of the fire largely determines whether new plants are sprouts or seedlings.

Where fire top-kills plants that can vegetatively regenerate, sprouting will be a significant source of postfire vegetation. Where lethal temperature penetrates deeply enough to kill many regenerative structures, sprouting may be limited, but some buried seed may receive the proper stimulus to germinate and produce significant numbers of seedlings. A microsite that sustained lethal heat deeply enough to kill all stored seed probably had enough fuel and duff consumed to prepare areas of bare mineral soil seedbed. Reproduction on these sites occurs from seeds dispersed onto these burned surfaces. The availability of canopy-stored seeds depends on the height to which lethal temperatures reached into the tree crowns, while dispersal from wind-carried offsite seeds depends on distance and direction of prevailing winds. Surviving trees and resprouting plants may produce seeds that can establish within the next few growing seasons while suitable seedbed exists.

The immediate response of plants can differ within the same fire because of variations in the pattern of burn severity. For example, chamise and redstem ceanothus can sprout after a low to moderate severity fire treatment. High severity fires kill existing plants but they are replaced by new plants that develop from fire-stimulated seeds. The postfire community may contain both sprouts and seedlings of these species with the proportion related to the severity of the fire.

Postfire species composition is usually an assemblage of many of the species that were growing on the site and represented in the seedbank at the time of the fire. Vegetative regeneration is common to many species and can make a major contribution to the postdisturbance community (Ingersoll and Wilson 1990), contrary to the commonly held notion that seed reproduction is dominant. Resprouts from rhizomes, root crowns, or protected meristems can account for a substantial proportion of postfire recruitment (Lyon and Stickney 1976). Many of the seedlings present in the first few postfire years may have grown from seeds formed on resprouting species such as fireweed and heartleaf arnica. The only locations in which new species are likely to be added to the plant community are microsites that are severely burned and receptive to germination and establishment of seeds from species dispersed from off of the site (Stickney 1999).

How This Applies to Management

Knowledge of plant response to fire can be critical to successful application of prescribed fire. Designing fire prescriptions requires knowledge of fire behavior, fire severity, species survival mechanisms, and methods of postfire vegetation recovery. Fire prescriptions should describe a set of weather and fuel moisture conditions that will control the rate and amount of fuel consumption by different size classes. Properly conducted, the prescribed fire will result in the desired amount of mortality, injury, resprouting, and seedling establishment from target species. To ensure that a desirable range of plant species establishes after prescribed fire, it is helpful to acquire predictive means of assessing how different prescriptions can produce different fire and plant responses (Whittle and others 1997). A fire prescription that takes both the surface and subsurface heat regime into account, thereby regulating its severity, is most likely to achieve desired fire effects.

How can you learn about the effects of fire and postfire response for individual plant species? The Fire Effects Information System is an Internet database that contains specific information about 900 plants from the United States and Canada (see chapter 9).

The best way to learn about fire effects in a specific location is to visit areas recently burned under different fire prescriptions and fuel and soil moisture conditions. Answers to the following check-list questions

can help you understand the type of fire treatment that will create the effects you desire:

Manager's Checklist

- Which species are present?
- How much injury did surviving plants sustain?
- Are there new plants of different species sprouts or seedlings?
- From what depths and structures did sprouting plants originate?
- Are seedlings rooted in organic or mineral substrate?
- Is there a pattern of sprouts and seedlings that is related to fuel and duff consumption?
- Is the species composition of seedlings related to canopy mortality or proximity to unburned areas?

Chapter 3: Fire in Northern Ecosystems

Mixed Fire Regime

Major Vegetation Types

Major forest types include those where aspen, eastern white and red pine stands, and jack pine stands are found either as fire-maintained seral types or exceptionally as climax stands (see table 3-1 for FRES, Kuchler, and SAF cover type designations). This includes extensive areas from Newfoundland across to Alaska and the Great Lakes region. Fire regime characteristics varied extensively for these major vegetation types, reflecting local and regional topography, fuel type and climate. Fire regime characteristics (summarized in table 3-1) are discussed by first describing distribution and site features of the major vegetation types followed by discussion of the nature of fire.

Fire Regime Characteristics

Aspen—With its continental distribution, aspen is the most widely distributed forest type in North America extending from Newfoundland to Alaska, then southward through the western mountains of Canada and United States to Mexico (Eyre 1980; Farrar 1995). Aspen-dominated ecosystems are generally found as seral and more rarely as climax ecosystems.

Aspen occurs mostly as a pioneer type (fig. 3-1, 3-2) on burns or clear-cut areas on a wide variety of soil types excluding only the driest sands and the wettest swamps (Eyre 1980). In eastern Canada, aspen is found in association with sugar maple, balsam fir, speckled alder, eastern white pine, and paper birch (Eyre 1980). The transition area between the northern boreal forest and the central North American grasslands is dominated by aspen in central Canada where most even-aged stands have a fire origin (Jones and DeByle 1985). This forest type, frequent in Manitoba south of Lake Winnipeg and in North Dakota and northwestern Minnesota, occurs as well stocked stands in the northern portion of its range, and dwindles into patches surrounding moist depressions and streams farther south. Aspen is found in association with bur oak and in wetter locations with balsam poplar. On alluvial soils of eastern Saskatchewan and Manitoba, aspen is associated with white elm, green ash, Manitoba maple, and eastern cottonwood. Farther west, pure stands of aspen are found in association with the chernozem soil zones of Saskatchewan and Alberta (Corns and Anna 1986). Within the southern part of the grasslands, patches of aspen parkland are found in moist depressions and on bluffs and hills. In its western range, aspen is found most frequently as pure stands or in association with various conifers such as Engelmann spruce, lodgepole pine, ponderosa pine, and Douglas-fir.

Table 3-1—Occurrence and frequency of presettlement fire regime types by Forest and Range Environmental Study (FRES) ecosystems, Kuchler potential natural vegetation classes (1975 map codes), and Society of American Foresters (SAF) cover types. Occurrence is an approximation of the proportion of a vegetation class represented by a fire regime type. Frequency is shown as fire interval classes defined by Hardy and others (1998) followed by a range in fire intervals where data are sufficient. The range is based on study data with extreme values disregarded. The vegetation classifications are aligned to show equivalents; however, some corresponding Kuchler and SAF types may not be shown.

^cThis type occurs primarily in Canada and was not defined by Kuchler.

^dAdded subdivision of FRES.

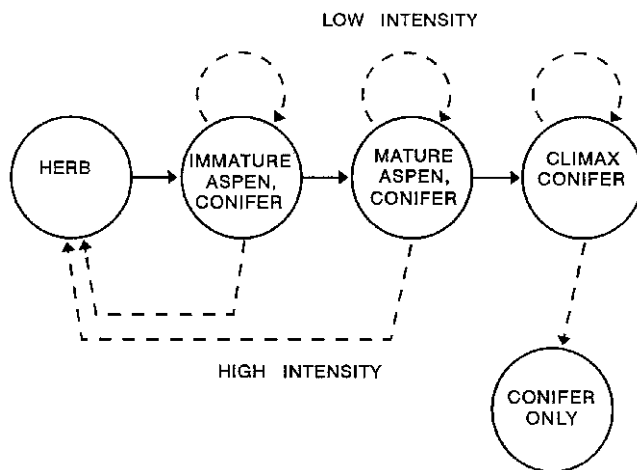

Figure 3-1—Successional pathways involving seral aspen, fire, and conifers (Brown 1985).

Pure aspen stands are particularly susceptible to mortality of aboveground stems from fire of low intensities, an unusual characteristic for a forest type so well adapted to regeneration after fire (Jones and DeByle 1985; Mutch 1970). Occasionally, fires of intensities greater than 30 Btu/ft/s (100 kW/m) have been shown not to damage mature trees (Quintillio and others 1989).

Paradoxically, aspen stands do not ignite easily and specific site and climatic conditions are necessary before fire can ignite and spread (Jones and DeByle 1985; Peterson and Peterson 1992; Wright and Bailey 1982). Generally, fires in young aspen stands are low intensity surface fires unless there is a great deal of fuel on the forest floor. In older stands, particularly those that are breaking up, abundant fuel can lead to higher intensity fires (Peterson and Peterson 1992).

White and Red Pine—Eastern white and red pine associations were generally fire-maintained seral types and existed occasionally as self-perpetuating climax under mixed fire regimes (fig. 3-3). The former include an extensive area associated with the Great-Lakes and St-Lawrence River ranging from Newfoundland to eastern Manitoba in Canada and New England, New York, Minnesota, Wisconsin, and Michigan in the United States (Eyre 1980; Farrar 1995; Roberts and Mallik 1994). Red and white pine were found in pure stands, or either species comprised the majority of stocking with jack pine, red oak, red maple, aspen, pin cherry, white spruce, and balsam fir. Pure red pine stands are mostly associated with dry, coarse soils whereas white pine tends to dominate in lighter structured soils (Eyre 1980).

Before fire protection, white and red pine stands were subjected to a mixture of lethal and nonlethal fires (Burgess and Methven 1977; Cwynar 1977, 1978;

Figure 3-2—Seral aspen stand in Ontario (Canadian Fire Danger Rating Group photo point).

Figure 3-3—White and red pine stand in Ontario (Canadian Fire Danger Rating Group photo point).

Frissell 1973; Heinselman 1981; Maissurow 1935, 1941; Methven 1973; Methven and Murray 1974; Van Wagner 1970; Wendel and Smith 1990). Pine stands on dry sites underwent a cycle of light to moderate fires every 20 to 40 years, then high intensity fires every 100 to 200 years. On mesic sites, white pine experienced mostly high intensity fires. Postfire survival depended on fire behavior and tree age. This burning pattern for white and red pine stands led to a negative exponential age-class distribution with approximately 55 percent of forest stands older than 125 years, and the pattern applies to landscapes at least 960,000 acres (400,000 ha) (Baker 1989), suggesting a large proportion of so-called old growth forests.

On dry sites, fire frequency varied from 20 to 300 years with an average return interval of approximately 100 years for the entire Great Lakes and St. Lawrence forest region (Bergeron and Brisson 1990; Burgess and Methven 1977; Cwynar 1977, 1978; Duchesne and Gauthier; Frissell 1973; Heinselman 1981; Maissurow 1935, 1941; Methven and Murray 1974; Rowe 1972; Van Wagner 1970) and from 15 to 30 years in Newfoundland (Roberts and Mallik 1994). Mesic sites colonized mainly by white pine were characterized by longer fire intervals, probably 200 to 300 years or more (Heinselman 1983).

Jack Pine—Jack pine forests (fig. 3-4) are a widespread ecosystem type extending across Canada from

Newfoundland to the Mackenzie river valley in the Northwest Territories (Eyre 1980; Farrar 1995), where they are found as fire-dominated pioneer stands. In the United States, jack pine stands are mainly found around the Great Lakes States, and less often in northern New England and New York. Typically, jack pine constitutes the majority of the stocking with several possible associate species. Associate tree species in the boreal forest are aspen, paper birch, balsam fir, and black spruce whereas, in the Great Lakes, they are northern pin oak, red pine, aspen, paper birch, balsam fir, and white pine (Eyre 1980). In general, jack pine stands are found on eskers, sand dunes, rock outcrops, clays, and organic soils. On the better sites, they exist primarily as pioneer stands but they tend to persist on xeric sites that are periodically visited by fire. Eyre (1980) recognized six variant types of jack pine:

1. Jack pine-balsam fir-black spruce in the mixed wood and hardwood forest zones of the boreal forest.
2. Jack pine-feather moss on clay and sands of the boreal forest.
3. Jack pine-sheep laurel on coarse sand and rocky outcrops of the mixed wood and coniferous forest zones.
4. Jack pine-Sphagnum on poorly drained organic deposits of the mixed wood and coniferous forest zones.
5. Jack pine-bog Labrador tea on well-drained deposits of a different nature in the coniferous forest zone.

Figure 3-4—Mature jack pine stand (Canadian Fire Danger Rating Group photo point).

6. Jack pine-lichen in the taiga on various kinds of deposits.

Fires in jack pine forests, as on most of the boreal forest, were dominated by crown fires or high intensity surface fires that cover broad areas (Van Wagner 1983) because of the climate, topography, and continuity of fuel. Fires were frequent on dry sites with average return intervals as low as 15 to 35 years in eastern Canada (Bergeron 1991; Heinzelman 1983) and the Great Lakes. Fire intervals were greater in the West (Heinzelman 1983). Exceptionally, jack pine is submitted to nonlethal understory fire regimes in insular situations (Bergeron 1991).

Fuels

Aspen—Aspen stands are only flammable in the spring, late summer, and fall when they are leafless due to the drying effect of sun and wind on the leaf litter. Furthermore, in the fall the herbaceous plant and shrub component of the understory is dead and dried out, forming a continuous layer of loosely organized fine fuel. In general flammability depends largely on the amount of herbaceous and shrub fuels present in the stand. Herbaceous fuels can vary from as little as 0.04 tons/acre to 0.75 tons/acre (0.08 t/ha to 1.60 t/ha). Shrub fuels range from 0 to over 2.25 tons/acre (0 to 4.80 t/ha) (Brown and Simmerman 1986). Forest

floor litter layer typically ranges from 0.38 to 2.9 tons/acre (0.80 to 6.60 t/ha) (Brown and Simmerman 1986; Quintilio and others. 1989).

White and Red Pine—White and red pine stands are fire-prone. Van Wagner (1970) reports that high density red pine stands are the most flammable fuel type of all northern cover types. The organic layer of white and red pine stands is generally 4 to 6 inches (10 to 15 cm) deep (Forestry Canada Fire Danger Group 1992). Light to moderate fires consumed the litter and shrubs along with invading shade tolerant conifers, but only scarred trees older than 30 to 75 years (Heinzelman 1983), whereas high intensity fires killed most trees. In addition to age, white and red pine survival to fires of all intensity varied according to rooting, fuel loading, density, and fire behavior. Trees with more than 75 percent crown damage were more likely to die within the first postfire year (Van Wagner 1970). Fuel loadings in white pine stands include approximately 7.1 and 11.1 tons/acre (15.9 and 24.8 t/ha) of woody surface fuel and forest floor material, respectively, and 5.3 and 10.5 tons/acre (11.8 and 23.6 t/ha) of woody surface fuel and forest floor material, respectively, for red pine (Stocks and others 1990).

Jack Pine—Immature jack pine stands are stocked with 4,000 to 12,000 stems/acre (10,000 to 30,000 stems/ha) and heavy thinning mortality results in a

large quantity of standing dead stems and down woody fuel, creating both horizontal and vertical continuity in the fuel. Fully stocked mature stands 400 to 800 stems/acre (1,000 to 2,000 stems/ha) have reached canopy closure and the base of the crown is separated from the ground. Surface woody fuel loadings vary from 2.9 to 17.2 tons/acre (6.5 to 38.6 t/ha) and forest floor loadings vary from 7.0 to 51.4 tons/acre (15.7 to 115 t/ha) (Quintilio and others 1977; Stocks 1989; Stocks and others 1990).

Postfire Plant Communities

Aspen

Pre-1900 Succession—Before settlement by Euro-Americans, large expanses of western aspen and aspen parkland existed in both the Canadian and American West. These stands were often perpetuated as a shrublike cover by light to moderate intensity fires that swept across the prairie grasslands and ignited the aspen stands on a regular 3 to 15 year basis. Aspen regenerated well after fire. Settlement of the West in the late 1800s and early 1900s increased fire frequency because of land clearing fires, slash burning, and railway traffic (Murphy 1985). In more recent times, following the implementation of rigorous fire protection programs, lack of fire has threatened the continued existence of aspen in the West (Brown and DeByle 1987, 1989; Peterson and Peterson 1992).

In the Rocky Mountains, low intensity fires caused thinning and encouraged all-aged stands whereas high intensity fires resulted in new even-aged stands. In early postfire communities aspen may be dominant but replacement of seral aspen by conifers is gradual and may take 200 to 400 years or more (Bartos and others 1983), depending on the potential for establishment and growth of conifers. Forage production declines two- to four-fold during succession.

Post 1900 Succession—Fire suppression since the 19th century has altered dynamics in aspen stands in the mountainous Western United States, changing fire frequencies from as little as 10 years (Meinecke 1929 in DeByle and others 1987) to approximately 12,000 years (DeByle and others 1987). Without the occurrence of disturbance, aspen clones mature in about 80 to 100 years (Schier 1975) and regeneration for this species is threatened. The dying back of those stands is now favoring shade-tolerant conifers or in some case grasses, forbs, or shrubs, depending on the availability of seed sources (Beetle 1974; Bergeron and Danserau 1993; DeByle 1976; DeByle and others 1987; Krebill 1972; Schier 1975).

Aspen stands may be replaced by conifers if subjected only to low intensity fires that do not kill conifer regeneration. Such conversion may require the absence of moderate to high intensity fire for as little as

one aspen generation to as long as 200 to 1,000 years in the southern boreal forest or in the Rocky Mountains (Bergeron and Dubuc 1989; J. K. Brown 1985; Brown and Simmerman 1986; Perala 1990).

Management Considerations—In those areas where the perpetuation of pure aspen stands is desired, prescribed burning can be an economical and ecologically sensitive silvicultural tool since it closely mimics the natural disturbance and regeneration patterns (Brown and DeByle 1987, 1989). Wildland fire use in wilderness areas and prescribed fire are the most acceptable management tools for maintaining aspen stands in the American West (DeByle and others 1987) and can be useful in aspen stands in the East as well (Perala 1974; Weber 1990). The timing and resulting intensity of the fires is critical because high intensity burns can reduce site productivity (Weber 1990). But also, low intensity fires may not spread adequately and with enough heat to kill most aspen resulting in a poor response of aspen suckers (Brown and DeByle 1987). The prescription window for successfully burning aspen tends to be narrow due to inherently low flammability. However, flammability varies substantially among aspen stands. Appraising flammability to recognize good burning opportunities can increase chances of success (Brown and Simmerman 1986). Thus, prescribed burners must be ready to act quickly when opportunities arise. Fuel enhancement by cutting some trees especially conifers to increase surface fuel loading and continuity can be helpful in some situations. In the Western United States, grazing by domestic stock and sometimes wild ungulates must be controlled to assure successful regeneration of aspen (Bartos and others 1994).

White and Red Pine

Pre-1900 Succession—Full succession of plant communities was not possible because of the fire regime associated with white and red pine stands. Recurrent nonlethal fires eliminated shade-tolerant competing vegetation and prepared seedbeds for trees. Red pine regeneration was probably more closely associated with high intensity fires than white pine regeneration because of red pine's greater intolerance to shade and humus. However, shading is required for optimal regeneration of both white and red pine. The resulting forest is an even-aged stand for both white and red pine. The within stand age-class distribution is greater for white pine than red pine based on repeated observations that white pine can regenerate well under a nurse crop if the seedbed is suitable (Eyre 1980).

Post-1900 Succession—As white and red pine stands mature, their regeneration fails to establish under cover, and tolerant species slowly invade. Without

fire, stands on dry sites evolve into mixed wood forests dominated by balsam fir and black spruce, or on mesic sites, white birch and aspen. White pine frequently pioneers on abandoned agricultural land, particularly in New England. However, in stands where fire is delayed for excessive periods, invasion by shade-tolerant species is a widespread phenomenon (Day and Carter 1990) leading to other forest types dominated by shade-tolerant species. After a high intensity 1995 wildfire in mature white and red pine stands in Quetico Provincial Park, red pine seedlings were present in low numbers but white pine seedlings were rare (Lynham and Curran 1998).

Management Considerations—Traditionally white and red pine stands were clear-cut (Mayall 1941) or clear-cut with residual seed trees at one to eight seed trees/acre (one to 20 seed trees/ha). However, competing vegetation, particularly beaked hazel and balsam fir on mesic sites, invade easily and prevent white and red pine from regenerating properly. This has led to a normal-shaped age-class distribution, contrasting strongly with a natural negative exponential distribution. Moreover, average age of white and red pine forests is now 72 years whereas pre-settlement average age was approximately 230 years. Shelterwood cutting is now the preferred silvicultural method for white pine management because it favors regeneration of white pine and to a lesser extent red pine, provided that mineral soil is bared.

Contrary to southern pine associations, fuel in white and red pine associations stabilizes after several years and there is no need for fuel control to prevent catastrophic fires. Furthermore, understory invasion by shade tolerant species has a negative impact on fire behavior by creating a layer of less flammable material (Van Wagner 1970).

Because white and red pine ecosystems are fire-prone and so dependent on fire for their regeneration, prescribed fire is an ideal silvicultural tool for regeneration and removal of competing vegetation (McRae and others 1998). Parameters of the Canadian Forest Fire Weather Index System (FWI) (Van Wagner 1987) that provide optimal results from prescribed burning in white and red pine stands have been determined to be (1) fine fuel moisture code 90 to 95, (2) initial spread index 8 to 16, (3) build up index up to 52, and (4) fire weather index 12 to 24 (Van Wagner and Methven 1977). Restoration forestry on rich sites may require two successive burns to eradicate resilient understory competition, particularly beaked hazel, and to prepare seed beds.

In the United States, low-intensity prescribed fire is the only practical treatment currently available to control white pine cone beetle that can ruin close to 100 percent of the cone crop in white pine seed orchards if not controlled. Wade and others (1990) developed

guidelines for using prescribed fire in seed orchards throughout the Eastern United States.

Jack Pine

Pre-1990 Succession—Owing to its serotinous cones, jack pine regenerated well following fire and its shade-tolerant understory associates were eliminated. Jack pine is a shade-intolerant short-lived, pioneer species that almost always grew in even-aged stands (Eyre 1980; Farrar and others 1954; Heinselman 1981). Seeds germinate best on mineral soil or highly reduced organic soil. Postfire growth was found to be favored on thin organic soils in Ontario (Weber and others 1987). However, in northern Quebec, postfire organic horizon thickness did not affect seedling growth (St-Pierre and others 1991). Without fire, jack pine forests are succeeded by balsam fir stands on xeric to mesic morainic surface deposits in the southern part of the Quebec boreal forest (Bergeron and Dubuc 1989). Alternatively, jack pine forests may be replaced by white spruce or black spruce in western Canada (Rowe and Scotter 1973; Wein 1983) and by balsam fir, aspen, paper birch, and eastern white cedar in eastern Canada (Bergeron and Dubuc 1989).

Post-1990 Succession—Fire suppression has a dramatic effect on the long-term productivity of jack pine associations. In the Northwest Territories, Wein (1983) described the possible impact of the absence of fire in boreal jack pine stands as follows. As soil organic matter builds up, jack pine becomes less vigorous and black spruce tends to move into the jack pine habitat until finally the organic matter becomes too deep or nutrients become too limiting for black spruce regeneration and black spruce is replaced by willow. In eastern Canada, old-aged stands of the boreal forest suffer from high levels of dieback and are transitory to associations dominated by black spruce or balsam fir (Cogbill 1985). In Michigan, the loss of extensive areas of dense, fire regenerated jack pine stands that existed prior to 1900 is the primary reason for the decline of the Kirtland's warbler, a species whose breeding habitat requires large tracts of 8 to 20 year-old jack pine associations (Radke and others 1989).

Management Considerations—Clear-cutting is the preferred harvesting method for jack pine. However, competing vegetation (particularly on the richer sites), insufficient seed rain, and thick humus can prevent development of proper stocking (Burns and Honkala 1990; Chrosiewicz 1990). In Quebec, and probably throughout the entire jack pine range, only 4 percent of jack pine stands have sufficient pre-established growth before clear-cutting (Doucet 1988). On the other hand, jack pine can regenerate well in clearcuts if 40 to 50 percent of treated areas display bare mineral soils and if branches are scattered evenly

over the terrain (Ball 1975; Chrosiewicz 1990). If planting is necessary, jack pine must be planted on site-prepared terrain (Beland and Bergeron 1993; Sutton and Weldon 1993).

Slash burning, together with seed tree systems, featuring approximately eight seed trees/acre (20 trees/ha) is the best method of regenerating jack pine after cutting (Chrosiewicz 1988, 1990). In addition, direct seeding has been shown to be successful on sites that have received prescribed burning (Cayford and McRae 1983). In practice, it was found that maximum regeneration can be achieved when burning occurs under the following conditions of the Canadian Forest Fire Danger Rating System: fire weather index of 4, duff moisture code of 37, fine fuel moisture code of 80, build up index of 58, and initial spread index of 1.2 (Chrosiewicz 1988). Regeneration of jack pine is best achieved by high intensity fires (>434 Btu/ft/s or >1500 kW/m) that consume most of the humus layer (Weber and others 1987).

Stand-Replacement Fire Regimes

Major Vegetation Types

Major vegetation types experiencing stand-replacing fire regimes include stands dominated by black

spruce, white spruce, red spruce, and balsam fir along with conifer bogs and tundra (table 3-1). All these types are characterized by stand-replacement fire regimes having different fire cycles that vary according to climate and topography. Stand-replacement fires are the most common type of fires in northern forests, sometimes becoming as large as 2.8 million acres (1.4 million ha) (Murphy and Tymstra 1986).

Fire Regime Characteristics

Black Spruce—Black spruce associations are widespread throughout the northern biome from Alaska to Newfoundland and from the northern limits of the tree line south into the northeastern and North-Central United States. This species is found on a wide variety of sites ranging from moderately dry (fig. 3-5) to very wet. At the southern portion of its range, black spruce is found primarily on wet organic soils, but farther north its abundance on uplands increases. In the Lakes States and in New England, black spruce is mostly found in peat bog and swamps.

In southern areas of the black spruce range, it is commonly associated with a variety of other tree species including balsam fir, paper birch, tamarack, and aspen (Hare 1954; Rowe 1972). The stocking and associated vegetation on organic peatland soils depends largely on water sources and movement (Eyre

Figure 3-5—Black spruce stand (Canadian Fire Danger Rating Group photo point).

1980). On moist sites, well stocked to dense stands of black spruce grow above a well-developed mat of feather mosses such as Schreber's moss, mountain fern moss, and knight's plume moss (Eyre 1980; Meades and Moores 1989). On very wet mineral or organic soils, the moss carpet is dominated by Sphagnum mosses. Typically, moist to very dry nutrient-poor sites are characterized by open stands of black spruce with the ground covered by species of Cladonia lichens. The shrub layer in these forests consists mainly of ericaceous plants such as sheep laurel and bog Labrador tea. The organic layer may exceed a depth of 8 to 12 inches (20 to 30 cm) and comprises branches, other woody debris, and a variety of slowly decomposing plant material (less than 2 percent of organic matter decays per year) (Van Cleve and others 1979). In interior and south central Alaska, black spruce is extremely common on cold, poorly drained sites (Viereck and Dyrness 1980).

Fires in boreal black spruce ecosystems are large and frequent owing to the flammable nature of the forest, continuity of fuel sources and continental climate conditions (Heinselman 1981; Viereck 1983). Most fires in black spruce associations are either severe ground fires or crown fires of sufficient intensity to damage aboveground vegetation including the black spruce overstory and all of the associated understory shrubs. Some of the organic soil component usually remains, but high intensity summer fires, during dry, windy climatic conditions may achieve sufficient intensity to burn off this entire layer and completely expose the mineral soil. When drought conditions are extreme the entire forest structure becomes highly flammable and burns readily. In less extreme conditions, the lichen-dominated black spruce forest burns while the moister and older feather moss-dominated stands or deciduous mixed wood areas remain unburned (Foster 1983).

In general, the fire rotation of black spruce forests tended to be relatively short in the West while it was longer eastward, in response to a moister climate. Estimates of fire rotations range from 50 to 100 years in northwestern Canada and Alaska (Heinselman 1983; Rowe and others 1974; Viereck 1983) and for eastern Canada, 500 years in southeastern Labrador (Foster 1983; Viereck 1983), and 480 years in western Newfoundland (Wilton and Evans 1974). The longer rotation in eastern areas of the Canadian boreal forest are probably the result of higher levels of precipitation, and the occurrence of natural firebreaks such as lakes and extensive areas of moist peatlands.

White Spruce—White spruce associations have a transcontinental range from Newfoundland and Labrador, west across Canada along the northern tree line to Hudson Bay, Northwest Territories, Yukon, and Alaska. From British Columbia the range extends

east through Alberta and Manitoba and south and east through northern Minnesota and Wisconsin, central Michigan, northeastern New York, and Maine. In the eastern forest, white spruce grows from sea level to elevations of about 5,000 feet (1,520 m) in pure stands or in mixed stands where it is the major component. Associated species include black spruce, paper birch, aspen, red spruce, and balsam fir. In eastern Canada and northern New England white spruce is a climax species. Closed pure white spruce stands and spruce-balsam fir occur sporadically throughout the boreal forest on moist and fresh soils, particularly on intermediate and low slopes (Burns and Honkala 1990; Eyre 1980).

Because mature white spruce forests accumulate large amounts of organic matter consisting of feather mosses, woody fuels, flaky barks, and shrubs, they are highly susceptible to fire. Also the crown and canopy structure with tree crowns extending nearly to the ground is ideal for ignition and propagation of crown fires (Rowe and Scotter 1973; Van Wagner 1983). In the boreal forest, the fire regime was characterized by crown fires or severe surface fires with a return interval averaging 50 to 150 years. Lightning caused most fires, especially in the months of July and August (Heinselman 1981). Fires could cover areas of 3 to 250 acres (1 to 100 ha), but the most ecologically significant fires were large, often thousands of acres. One of the longest fire cycles, 300 years, characterized the flood plain white spruce forests. In the East cycles may average 150 to 300 years. In British Columbia, Hawkes and others (1997a) reported fire cycles ranging from 794 to 2,083 years for the wet, cool sites of white/englemann spruce-subalpine fir forests in the northern Rocky Mountains. The dry, cool sites of white spruce/aspen forests (Kluane Section, B.26d, of the boreal region; Rowe 1972) in Kluane National Park, Yukon, had mean fire return intervals ranging from 113 to 238 years while individual stand intervals ranged from 9 to 403 years. Francis (1996) reported that white spruce dominated forests of the Shakhwak Trench, Yukon, were characterized by large-scale, infrequent fire disturbances on north slopes while the south-slopes had small to medium-scale, frequent disturbances.

Balsam Fir—Balsam fir associations are found throughout eastern and central Canada as a band stretching from Newfoundland and central Labrador south to New York in the east and to central and northern Alberta in the west (Hosie 1973). Balsam fir is found in pure stands, and also in association with many species common to moist and wet sites where the ground-covering feather mosses build layers from less than an inch (a few centimeters) to more than 1 foot (30 cm) in thickness depending on stand maturity.

Balsam fir is a shade tolerant and late successional species. In the Eastern forests important associates were red spruce (mainly in New Brunswick and Maine) and paper birch. In the boreal forest region, it was more commonly found with black spruce, white spruce, jack pine, paper birch and trembling aspen. Balsam fir occurred on a wide range of soils including heavy clays, loams, and sandy glacial till. It was a climax association on upper slopes and tops of mountains (Burns and Honkala 1990; Eyre 1980).

In the high precipitation areas of eastern Canada and the Northeastern States, fire cycles were between 150 to 300 years (Heinselman 1981; Wein and Moore 1977, 1979). Stand-killing crown fires of high intensity or severe surface fires occur often after long droughts (Heinselman 1981; Rowe 1983; Van Wagner 1983). Unique spatial arrangements and dry conditions are responsible for several smaller, nonstand replacing fires of lower intensities, every 20 to 30 years in northwestern Quebec (Dansereau and Bergeron 1993). The periodic outbreak of the spruce budworm (*Choristoneura fumiferana*) causes heavy tree mortality (fig. 3-6), leading to a large fire potential peaking 5 to 8 years after tree death. However, the flammability of such forests decreases gradually after that period as balsam fir fuel starts to decompose and understory vegetation proliferates (Stocks 1987).

Red Spruce—Red spruce was one of the more important conifers in the Northeastern United States and adjacent Canadian provinces. Red spruce was most abundant in the Maritime Provinces, neighboring portions of Quebec, south-central Ontario and in parts of Eastern North America but especially in Maine. It grows best in a cool, moist climate, in either pure stands or as a major component of the growing stock. In the northern part of its range, red spruce grows at elevations from near sea level to about 4,600 feet (1,400 m). In mixed stands other common associates were red maple, eastern hemlock, eastern white pine, white spruce, eastern white cedar, and black spruce (on wet sites). Red spruce stands are found over a range of sites including moderately well drained to poorly drained flats and the thin-soiled upper slopes. On acidic tills it is considered climax. It is present on fresh and moist acidic outwash and on well drained slopes and varying acidic soils in abandoned fields and pastures where it is usually subclimax (Eyre 1980) being replaced by shade-tolerant hardwoods such as sugar maple and beech.

The ground cover in dense red spruce stands consisted mostly of bryophytes, lichens, tree litter, and patches of young conifer germinants that rarely survive over 2 or 3 years. As stands opened up and light conditions improved additional arboreal species,

Figure 3-6—Aerial photograph of a Balsam fir stand after infestation by spruce budworm (Canadian Fire Danger Rating Group photo point).

shrubs, and herbs developed. The three main associations—*Hylocomium/Oxalis*, *Oxalis/Cornus*, and *Viburnum/Oxalis*—indicate increasing site productivity and increasing hardwood competition. The *Oxalis/Cornus* association is considered the best for growing conditions (Eyre 1980). Presettlement fire rotations in red spruce associations averaged 100 to 150 years and higher (Heinselman 1981; Wein and Moore 1977, 1979).

Conifer Bogs—Conifer bogs are found over a wide range of soil and climatic conditions in Canada, and the North-Central United States and Alaska. Tree height, stand density, and especially floristic composition can differ considerably. Stand density varies from open to well-stocked stands. Composition can range from pure black spruce, tamarack, or eastern white cedar stands to black spruce in association with tamarack, balsam fir, eastern white cedar, paper birch, speckled alder, black ash, poplar, and willow (Armson 1982; Bergeron and Dubuc 1989; Eyre 1980; Johnston 1975, 1976).

Black spruce-dominated bogs, the most abundant bog type, are widely distributed throughout the boreal forest from Newfoundland to Alaska and south into the Great Lakes-St. Lawrence Region. Tamarack bogs, or wetlands stocked mainly with tamarack, are found from Quebec across the boreal forest to northwestern Alberta, south into the Lake States, and large portions of Minnesota, New York and New England. Pure eastern white cedar or eastern white cedar dominated bogs are limited to southern Ontario, Quebec and New Brunswick, the Lake States, and Northeastern States (Eyre 1980).

In general, conifer bogs are not as fire-prone as other forest stand types because of their wetter nature (Heinselman 1973, 1981; Payette and others 1989; Rowe and Scotter 1973). The high water table in the spring, a green dense understory, and a more humid environment render conifer bogs unsusceptible to forest fire except in severe drought years. These conditions, favoring low decomposition rates, enable the formation of an organic layer that can become greater than 3 feet (1 m) thick (Heinselman 1981). In turn, the thick organic layer of conifer bogs maintains a high moisture content that further contributes to the longer fire cycle of bog sites (Heinselman 1981; Rowe and Scotter 1973).

A second characteristic of bogs that tends to exclude fire from them is their tendency to occupy depressions and lowland areas. Because conifer bogs are mainly located in convex depressions, they are avoided by fire, which seeks convex landforms such as hilltops and slopes (Payette and others 1989; Rowe and Scotter 1973). Consequently, bog sites are spared from even large, high intensity forest fires, leaving unburned pockets of forests that become important seed sources

to accompanying uplands (Bergeron and Dubuc 1989; Payette and others 1989).

Fire in conifer bogs occurs mostly in July, August, or September during severe drought years when a low water table allows the forest floor to become thoroughly desiccated. Under these circumstances with sufficient wind, spruce, tamarack, and eastern white cedar trees of conifer bogs can sustain major crown fires. Heinselman (1981) estimated the fire rotation to be 100 to 150 years for large forested spruce bogs in Minnesota. He found that the average fire rotation of spruce bogs is longer than those of nearby upland forests.

Tundra—Tundra ecosystems can be separated into three main types: (1) arctic tundra occurring at high altitudes and low elevations, (2) alpine tundra occurring at higher elevations farther south, and (3) the sedge tussock-mixed shrub in Alaska, throughout the Seward Peninsula and interior. Whereas vegetation is similar in the first two types of tundra, they differ mostly in climatological factors such as maximum summer temperatures, extremes of day length, and intensity of solar radiation (Barbour and others 1980). In the three tundra types, the upper to 6 to 24 inches (15 to 60 cm) of soil is subjected to a seasonal freeze and thaw cycle. This layer, called the active layer, lies above the permafrost layer (Barbour and others 1980). Vegetation is short, often only 6 inches (15 cm) tall, and is dominated by perennial forbs, grasses, sedges, dwarf shrubs, mosses, and lichens (Barbour and others 1980; Brown 1983). Herbaceous perennials make up 95 to 99 percent of the tundra flora and 60 percent of these are hemicryptophytes (perennials with perennating buds just at the soil surface).

In general, distribution of vegetation over the tundra biome is characterized by a patchy occurrence of dense vegetation, sparse vegetation, and bare ground offering an interrupted fuel bed (Payette and others 1989). However, in the sedge tussock-mixed shrub tundra, the fuel layer, made up mostly of sheathed cottonsedge, is dense and continuous leading to large, fast spreading conflagrations (Racine and others 1987).

The transition zone between the upper limit of the boreal forest and the tundra has been distinguished as forest tundra and is characterized by a fragmented cover of scattered forest stands of lichen-spruce and lichen-heath communities on well-drained sites. The forest tundra is further delineated into the forest subzone and shrub subzone (Payette and others 1989; Sirois and Payette 1991). In both the forest tundra and tundra, the ground vegetation is the primary carrier of fire. Lichens resemble dead tissue more than live tissue in their susceptibility to fire and often serve as the initial point of ignition. The low shrub component can provide a high percentage of fine, dry fuel with a low temperature of ignition (Auclair 1983).

Burning patterns of tundra ecosystems generally are characterized by moderate intensity surface fires that may kill all aboveground plant parts but seldom destroy underground parts (Bliss and Wein 1972; Van Wagner 1983; Viereck and Schandelmeier 1980). The fire cycle may be as short as 100 years, but it is usually much longer (Viereck and Schandelmeier 1980). According to Sirois and Payette (1991) and Payette and others (1989), the modern fire rotation period increases from 100 years in the upper boreal forest to 180 to 1,460 years in the forest subzone and to 9,320 years in the shrub subzone of the forest tundra of northern Quebec. Tundra west of Hudson Bay is more influenced by a continental climate and is more likely to burn and therefore have a shorter fire rotation (Payette and others 1989). In addition, the tussock-sedge tundra of Alaska may be a fire-dominated ecosystem, although the fire interval has yet to be determined (Racine and others 1987).

The long fire rotations in the tundra are probably related to the prevalence of cold, humid summers, saturated peat profiles, and the absence of continuous vegetation cover. These features serve to restrict fire spread over a large area (Payette and others 1989). In northern Quebec, small sized fires (<120 acres or <50 ha) occurred more frequently in the tundra than in the forest tundra; and forest tundra fires were smaller, on average, than boreal forest fires. Some large fires overlapped the limit between the biomes of the northern boreal forest and the forest tundra, but there was no overlapping between the forest tundra and the shrub tundra (Payette and others 1989).

Fuels

Black Spruce—The Canadian Forest Service's Fire Behaviour Prediction system recognizes two fuel types associated with spruce forests (Forestry Canada Fire Danger Group 1992). In spruce-lichen woodlands (fuel type C1), the lichens that dominate the ground cover are exposed to sunlight and, with no vascular tissue, dry out easily (Auclair 1983). These dry lichens form a mat 0.75 to 1.5 inches (2 to 4 cm) thick and combine with a variety of woody debris and shrubs to form a highly flammable ground fuel (Johnson 1992). Furthermore, spruce-lichen woodlands without a closed canopy permit the passage of wind, thus enhancing the rate of fuel drying; and once a burn is initiated, wind passage carries fire and augments radiant heat transfer (Foster 1983). Alexander and others (1991) reported that wind tilts the flame easily in the lichen layer but a high-intensity flame radiation surface fire does not develop. The combination of the lichen layer and scattered black spruce tree clumps produce high-intensity fires with spread rates from 2.0 to 168 ft/min (0.6 to 51 m/min) and fire intensities of nearly 9,540 btu/ft/s (33,000 kW/m).

The boreal spruce fuel type (C2), the second black spruce fuel type, consists of a continuous mat of feather moss, lichens, moderate amounts of woody debris and a well developed ericaceous shrub layer. This fuel type can become highly flammable when it is dry. However, when forming a wet peatland, it is not readily flammable and can act as a firebreak (Foster 1983). This fuel type typically occurs in old, closed canopy black spruce stands where the mineral soil may remain frozen for most of the year (Foster 1983) because it is covered by a thick (4 to 8 inches; 10 to 20 cm) moss layer lying over a substantial accumulation of humus (6 to 12 inches; 15 to 30 cm). These sites are less prone to drying than the spruce-lichen woodlands because the ground fuel receives less radiant energy and less wind (Foster 1983; Viereck 1983). The tendency of black spruce to hold dead branches along the entire length of their stems provides a fuel ladder for fire to spread from the flammable shrub layer up into the crown in both fuel types (Viereck 1983).

In Alaska, open canopy black spruce with feather moss, lichens, low shrubs, and little woody debris is a common forest type (Viereck and Dyrness 1980). In such associations, the shrub layer is not an important part of the fuel ladder since fire bridges from the moss-lichen layer into the spruce crowns. In fuel studies surface woody fuels varied from 0.67 to 20.0 tons/acre (1.50 to 44.9 t/ha) and forest floor varies from 5.4 to 23.8 tons/acre (12.2 to 53.4 t/ha) (Dyrness and Norum 1983; Kiil 1975; Stocks and others 1990).

White Spruce—Mature northern white spruce stands have well developed moss layers, mostly mountain fern moss, Schreber's moss, knights plume moss, dicranum moss, and sphagnum. In northern Ontario, surface woody fuels varied from 10.9 to 13.1 tons/acre (25.3 to 32.4 t/ha) and forest floor varied from 19.6 to 111.1 tons/acre (45.6 to 53.8 t/ha) (Stocks and others 1990). In the British Columbia Rocky Mountains, surface woody fuels varied from 17.1 to 69.1 tons/acre (38.3 to 155.5 t/ha) and forest floor varied from 23.3 to 61.5 tons/acre (52.3 to 137.7 t/ha) (Hawkes 1979; Hawkes and others 1997b).

Balsam Fir—Fire behavior in budworm-killed stands differs greatly between spring and summer. To illustrate, spring fires resulted in sustained crowning and spotting with extremely fast spread rates whereas the summer fires were unable to sustain themselves and did not spread. The major reason for this difference seems to be a proliferation of lush green understory vegetation in the summer due to crown openings (Stocks 1987; Stocks and Bradshaw 1981).

Spring fires in balsam fir stands within the boreal and Great Lakes-St. Lawrence forest regions fires were common. They behaved explosively with continuous crowning, high spread rates, and severe downwind spot fires that killed and regenerated entire

stands. But they seldom burned much of the organic layer because it is still cold and wet (Heinselman 1981; Rowe and Scotter 1973). Summer fires were much more likely to consume the organic layer. Surface woody fuels varied from 6.53 to 17.4 tons/acre (14.5 to 38.7 t/ha) and forest floor loading varies from 6.53 to 32.7 tons/acre (18.7 to 52.8 t/ha) (Stocks and others 1990).

Red Spruce—Under drought and extreme fire weather conditions, fires of high intensity covering large areas or severe surface fires were possible. In old stands where red spruce was associated with balsam fir the periodic outbreak of the spruce budworm caused heavy tree mortality. This made these stands more susceptible to wildfires due to crown breakage and the proliferation of highly flammable fine fuels such as needles, dry twigs, and bark (insect-wildfire hypothesis) (Furyaev and others 1983). Fire potential is greatest 5 to 8 years after tree mortality. During this period, fires of great intensities tend to spread quickly due to evenly distributed fuel. To our knowledge, fuel loadings have not been reported in the literature for red spruce ecosystems. Presumably they are comparable to those of black spruce and white spruce ecosystems.

Conifer Bogs and Tundra—Fuel loadings in conifer bogs are highly variable because of the multiple species combinations found in this forest type. Fuel loadings for tundra are extremely variable, ranging from nearly nothing in tundra barrens to a maximum of 375 lb/acre (400 kg/ha) in Alaskan sheathed cotton-sedge communities (Ranice and others 1987).

Postfire Plant Communities

Black Spruce

Pre-1900 Succession—The semiserotinous cones of black spruce, located near the main stem, act as a potential seed bank from which seeds are dispersed after fire (Johnson 1992). Once open the cones release seed for 2 to 3 years following fire. Black spruce is relatively slow-growing and is best suited to mineral soils. However, the seedling and sapling stages are relatively shade tolerant, allowing black spruce to establish well even on organic soil.

Revegetation following fire usually follows one of two basic paths. On moderate to moist relatively fertile soils, black spruce feather moss succession dominates (Black and Bliss 1978; Viereck 1983; Wein 1975). After high severity fires that expose mineral soil, bryophytes and herbs dominate while black spruce seedlings establish. On the less severely burned sites, herbs and shrubs develop from rhizomes that were not killed by fire. This initial re-establishment lasts for up to 4 years, and although black spruce becomes established at this time, the shrub layer may dominate the

site for the first 25 postfire years. Eventually, the shade-tolerant black spruce, often growing at densities up to 12,000 stems/acre (28,800 stems/ha) (Viereck 1983) outcompetes the shrub layer and forms the canopy.

The second regeneration path begins with the establishment of black spruce with mosses, lichens, and in some cases grasses. After 10 to 60 years, the ground cover on such sites is dominated by fruticose lichens along with low ericaceous shrubs (Black and Bliss 1978; Viereck 1983). During this phase, the black spruce component eventually forms an open canopy until approximately 100 years after fire, a typical black spruce lichen association is developed (Viereck 1983).

Post-1900 Succession—In much of the Canadian and Alaskan boreal forest, fire regimes and postfire communities remain similar to the presettlement period due to remoteness and lack of access. Most fire disturbed stands eventually regenerate back into black spruce ecosystems just as they would have before effective fire suppression. In areas undergoing commercial harvest, slash material and improved access (and resulting human activities) may combine to cause more frequent and more severe fires than in the period preceding fire suppression (Heinselman 1981). Fire protection has lengthened fire rotation from 120 to 200 years in spruce lichen forest and from 100 to 150 years in closed black spruce stands of Northwestern Canada and Alaska (Viereck 1973). In Ontario and Quebec, fire protection has increased fire rotations from 50 to 100 years to approximately 90 to 150 years (Heinselman 1981).

Management Considerations—Large-scale commercial harvest of black spruce and its associated species in Canada is one of the single most important industrial activities in the boreal forest. The resultant emphasis on protection of black spruce stands from insect and fire damage has generally increased the fire rotation in black spruce, particularly in protected forest reserves (Heinselman 1981; Viereck 1983). Harvest scheduling of high risk stands (high fire component; older or senescent stands) is a strategy that has also been used to reduce fire risks. In Alaska, black spruce stands occur mostly on permafrost with low stand productivity and are a low priority for fire protection.

Where fire exclusion is practiced, the flammable nature of black spruce ecosystems combined with their remoteness present major problems to fire managers (Viereck 1983). In spruce-lichen woodlands, drying occurs rapidly (Auclair 1983; Johnson 1992) causing high fire hazard throughout the spring, summer, and fall. In spruce-feather moss ecosystems, particularly in the East, higher moisture levels reduce fire hazards. However, periodic droughts allow large tracts of this forest type to burn (Heinselman 1981).

Prescribed fire in black spruce cannot be used in areas with shallow soil profiles as soil conservation is a major concern in such sites. In low-lying Sphagnum-dominated sites, fire is usually not required for seedbed preparation as black spruce seeds easily germinate on the Sphagnum bed itself (Archibald and Baker 1989). In lowland spruce-feather moss stands, moderate to high severity fires are required to remove the feather moss layer, slash, and litter to prepare the seedbed. When heavy competition from alder or other boreal hardwoods is present, high severity burns are required to kill off the subterranean rhizomes of the unwanted species, although if herbicides are applied before the burn, low to moderate severity fires may suffice (Archibald and Baker 1989).

The weather indices used for prescribed burns vary with silvicultural goals. In northwestern Ontario, low severity fires designed to burn fine fuels without removing large amounts of duff require a duff moisture code of 4 to 10 and a buildup index of 15 to 19. Moderate severity burns for the purpose of removing fine fuels, some heavy fuels and patches of duff require a duff moisture code of 8 to 16 and build up index of 18 to 28. Severe fires removing both fine and heavy fuels as well as 0.5 to 1.5 inch (1 to 4 cm) of duff require a duff moisture code of 13 to 25 and a build up index of 24 to 45 (Archibald and Baker 1989). Quantitative slash and forest floor consumption can be predicted using tables developed for lowland and upland black spruce forest by McRae (1980).

White Spruce

Pre-1900 Succession—Depending on seed rain, white spruce stocking may either decrease or increase in postfire communities. Seed production varies greatly from year to year with good seed crops every third year or so. Cones mature in late August or September and the majority of the seeds fall soon thereafter. So postfire regeneration of white spruce is increased when fire occurs in late summer of a good seed year. Otherwise, the only available seeds come from unburned patches or the edge of the burn (Dix and Swan 1971).

Feather mosses and lichens are eliminated wherever the moss layer has burned but reappear 10 to 15 years after fire and often reach high ground coverage within 50 years. If only white spruce is present in the prefire community, and seed trees are eliminated over large areas, an initial establishment of aspen seedlings may occur, thus slowing the reestablishment of white spruce (Van Cleve and Viereck 1981).

Post-1900 Succession—Past fires, logging, and land-clearing in the Northeastern forests caused white spruce associations to be replaced with aspen. The successional trend for such stands is generally toward spruce-fir and, where soil and climatic conditions

permit, toward northern hardwoods. Fire suppression and control in Alberta allow stands to mature and succession favors shade-tolerant species such as balsam fir and tolerant hardwoods (Weetman 1983).

Management Considerations—Clearcutting is the usual harvesting method for white spruce ecosystems. Clearcutting followed by broadcast slash burning results in the most marked changes in vegetation and soil temperature. Experiments in Alaska showed that many of the species present before disturbance disappeared afterwards (Dyrness and others 1988). Soil temperature increased on clearcut and shelterwood sites, but not as much as on clearcut and burned areas. Thinning had the least impact on vegetation and soil temperature (Dyrness and others 1988). Prescribed fire is effective in reducing heavy slash, seedbed preparation, controlling unwanted vegetation, and promoting vigor in desired species. Because white spruce is particularly sensitive to environmental conditions during germination and early growth, it is among the most difficult conifer species to regenerate naturally. However, summer logging or scarification that exposes mineral soil seems to improve regeneration (Brand and Janas 1988; Eis 1965, 1967; Endean and Johnstone 1974).

Natural white spruce stands can respond well to cultural practices, especially releasing. White spruce stands should be maintained at basal areas from 100 to 140 ft²/acre (23.0 to 32.1 m²/ha) to provide maximum volume growth and good individual tree development. Below these levels, individual tree increment and resistance to some pests are greatly increased, whereas total volume production is reduced (Burns and Honkala 1990).

Balsam Fir

Pre-1900 Succession—Owing to the high sensitivity of this species to fire, balsam fir survives only extremely low intensity fires or in patches of unburned forest. Even if trees are only damaged, fungal diseases and insect attacks will quickly destroy the stand structure. Following canopy opening by a first fire, a second fire can cause even greater changes in species composition (Little 1974).

Long fire cycles allow establishment of old-growth stands dominated by shade-tolerant balsam fir regeneration, a condition that is most abundant about 100 years after fire (Heinselman 1973). Because balsam fir has little fire tolerance, fire in balsam fir dominated forests tends to eliminate most of the existing stems and favors conversion to other tree species. Accordingly, fire in black spruce-balsam fir stands tends to favor the black spruce component (Candy 1951; Damman 1964; MacLean 1960). In the absence of conifer seed trees, postfire communities are dominated first by

aspen or paper birch seedlings that originate from wind-borne seeds. Subsequently, white or red spruce seedlings invade the burns, developing as an understory to the aspen-birch complex and eventually replace it. On some of the better sites, northern hardwoods such as sugar maple and beech eventually replace white spruce. Alternatively, balsam fir dominates (Day 1972).

Post-1900 Succession—Fire protection, coupled with clear-cut logging have favored the establishment of pure balsam fir associations. The shade-tolerant seedlings of balsam fir establish well in the shade of balsam fir or spruce stands. Thus, following logging, pre-established balsam fir generally dominates in the regenerating stand. However, in some situations, bracken fern, raspberry, and hardwood suckers may represent intense competition to the balsam fir regeneration for the first 10 to 25 years after disturbance (Burns and Honkala 1990). Repeated burns or cutting and burning in Newfoundland can lead to the development of *Kalmia* barrens or heathland conditions (Damman 1964), which once established are difficult to reforest. Black spruce invades such sites due to poor seed supplies of balsam fir and soil deterioration (Damman 1964).

Management Considerations—Clearcut logging has been the most used harvesting method for this forest type. However, site characteristics, the time of season, logging practices and size of the cut area are important factors to prevent damage for the pre-established regeneration of most spruce and fir stands, especially in the boreal region. A study in northwestern Quebec has shown that there is a deterioration in stand quality and a severe softwood mortality (92 percent) after harvesting and a shift in species composition from softwood-dominated advance regeneration to mixed or hardwood and shrub-dominated secondary forests. Often, it will be necessary to treat the area if the softwood crop is desired. Silvicultural treatments include scarification, direct seeding, planting, brush control, and subsequent thinning.

Overmature balsam fir forests (about 100 years of age) are susceptible to spruce budworm infestations (Heinselman 1973). Silvicultural options include harvest or protection against spruce budworm outbreaks, which involves the use of chemical or biological insecticides (Dimond and others 1984). Budworm outbreaks have serious economical and social impacts on forest industry. Accordingly, there is interest in converting fir forests in eastern Canada that are susceptible to spruce budworm to less susceptible species, particularly black spruce. Species conversion requires intensive site preparation owing to the presence of understory fir regeneration that provides strong competition

to planted spruce seedlings on many sites. A cost-effective method of site preparation is prescribed burning, which eliminates fir regeneration completely and favorably prepares the site for spruce seedlings. Prescribed burning in balsam fir forests could also be used for removal of slash prior to planting, or for reduction of fire hazard (Furyaev and others 1983). Prescribed burning in budworm-killed forests has been applied in Ontario (Stocks 1987) and in Quebec (Robitaille 1994).

Red Spruce

Pre-1900 Succession—Red spruce was a late successional species forming old-growth stands in areas with long fire cycles (Burns and Honkala 1990). Its shallow root system, thin bark, and flammable needles make trees of all ages susceptible to fire damage. Natural reproduction of red spruce depends on seedling survival since seedlings have an exceptionally slow-growing, fibrous, and shallow root system. A critical factor for their survival and establishment is the depth of the organic layer. Although a shade-tolerant species, the relative tolerance of red spruce to shade varies with soil fertility and climate. At first, seed germination and initial seedling establishment proceed best under cover. However, older seedlings require 50 percent or more sunlight for optimum growth (Burns and Honkala 1990).

Red spruce's chief competition comes from balsam fir and hardwoods such as beech and maple. Red spruce seems to respond to release even after many years of suppression (up to 100 years). Nevertheless, many of its associated tree species such as balsam fir and hemlock may outgrow red spruce after release (Burns and Honkala 1990).

Post-1900 Succession—Clearcutting had a serious impact on red spruce ecosystems. Many former spruce sites are now occupied by inferior tree species, blackberries, and ferns. Dense growth of bracken, raspberry, and hardwood sprouts are the chief competition for seedlings on cutover lands (Burns and Honkala 1990). Logging and fire in the Maritimes has left large areas of red spruce stands in poor conditions in terms nutrient status and species composition, leading to poor growth and conversion to heathlands. In turn, this has caused shortages of saw timber and pulpwood (Weetman 1983).

Management Considerations—Red spruce may be grown successfully using even-aged silvicultural prescriptions. Because red spruce is shallow-rooted, it is highly sensitive to windthrow. To minimize the danger of wind damage, it is recommended that no more than one-fourth to one-half of the basal area, depending on site, be removed in the partial harvest of a spruce-fir stand (Frank and Blum 1978).

Conifer Bogs

Pre-1900 Succession—There are two different views on the effect of fire on cold northern bogs. Rowe and Scotter (1973) describe how fire can contribute to site paludification. Fire removes the transpiring crowns, the water table rises, light levels increase on the ground floor, which promotes the establishment of *Sphagnum* mosses. Then moss layers build up, insulating the soil and lowering soil temperature. All of these fire effects create poor seedbed and poor rooting conditions for trees, thus excluding tree establishment and leading to a tundra type community. Conversely, Heinselman (1981) found that prolonged fire-free intervals cause a rise in permafrost tables, impede soil drainage and general site degradation. The result is a depauperate black spruce muskeg (Heinselman 1981). Strang (1973) found the same successional pattern in northern open black spruce-lichen associations.

Spruce-Sphagnum bogs that have been destroyed by fire are replaced by birch and other pioneer species, then evolve to a stage where both birch and spruce are present and, finally, to the spruce stage at which paludification begins (Larsen 1980). However, recurrence of fire in conifer bogs prevents most stands from reaching their climax stage (Bergeron and Dubuc 1989; Heinselman 1973, 1981).

Lightning was, and still is, a major cause of fire in the boreal forest. Lightning strikes during rainless storms during prolonged summer droughts ignite major fires to which conifer bogs are most susceptible. Such fires expose the mineral soil and create seedbed conditions conducive to the regeneration of conifer bog species (Heinselman 1981).

Spring and fall fires become more common in the boreal forest with increased human activity. Such fires have relatively little effect on reducing the duff layer and subsequently produce poor seedbed conditions for conifer bog species (Heinselman 1981; Viereck and Johnston 1990). Lightning fires are probably still responsible for most of the annual area burned.

Before 1900, fire prevented high concentrations of dwarf-mistletoe on black spruce because this parasite is temporarily eliminated when fire removes its host. Therefore fire was able to eradicate centers of infestation, thus preventing this disease from spreading. Current fire exclusion policies favor vast expansions of mistletoe (Heinselman 1973).

Post-1900 Successions—Human influence on conifer bog sites has been somewhat limited because most bogs have poor timber productivity. Most anthropogenic influence arises from the harvesting of surrounding stands and the side effects of fire protection on those same higher value sites. The policy of fire protection has lengthened the fire cycle for the boreal

forest and, therefore, the fire cycle of nearby bog sites (Heinselman 1981).

Management Considerations—Management practices in conifer bogs depend greatly on site productivity. Poorly drained, wet sites have such low wood productivity that little silvicultural management is done in these conifer bogs (Viereck and Johnston 1990). For the more productive peatland black spruce sites, clear-cutting in strips or patches, combined with broadcast burning of slash, followed by direct or natural seeding, is the best silvicultural treatment (Johnston 1975; Viereck and Johnston 1990). This same system works well for northern white cedar, but shelterwood management is preferred as it supplies partial shade for establishing seedlings (Johnston 1990b).

The shade-intolerance of tamarack dictates the use of even-aged management, with some adaptation of clearcutting or seed tree cutting generally considered the best silvicultural system (Johnston 1990a). Uneven or all-aged management is best applied to poor black spruce sites where stands are wind firm and have abundant layering (Viereck and Johnston 1990). Prescribed burning improves seedbed conditions and kills back competing brush (Armson 1982; Johnston 1973, 1975, 1976). However, tamarack slash is difficult to burn (Johnston 1973, 1975). Seedling survival is substantially greater on prescribed burn sites.

Tundra

Pre-1900 Succession—Fire effects in tundra ecosystems vary greatly according to the composition of prefire plant communities (Bliss and Wein 1971). Generally, fire favors rapidly growing species, particularly graminoids, and there is a decreased abundance of slow growing species such as evergreen shrubs immediately following fire (Bliss and Wein 1971, 1972). The recovery of mosses and lichens is slow as opposed to that of sedges and grasses, and recovery of shrubs is intermediate (Bliss and Wein 1972). Postfire regeneration is reliable because all shrubs and deciduous tree species common to the tundra are capable of reproducing vegetatively after fire (Auclair 1983; Viereck and Schandelmeier 1980). Establishment of pioneer species is mainly by wind-borne seeds from adjacent plant communities (Auclair 1983). Most lichens establish by small thallus fragments within the first several years following a burn, but their slow growth limits their abundance for the first 25 to 30 years (Auclair 1983).

The forest tundra zone is transitional, depending on fire cycle and fire severity (Viereck and Schandelmeier 1980). Sirois and Payette (1991) suggested that recurring fire progressively decreases the regenerative potential of trees and that sustained depletion of tree

populations following several fires is a key process in the development of the forest tundra. In the shrub subzone of the forest tundra where tree regeneration is tenuous, a single fire event can eradicate the presence of trees and creates treeless tundra. The boreal forest-forest tundra interface may be prone to sudden fragmentation caused by fire and climate interactions (Sirois and Payette 1991). Severe fires causing depletions of trees resulting in shifts from forest to forest-tundra communities have been reported from subalpine sites in Western North America and subarctic sites in northern Sweden and northern North America (Sirois and Payette 1991).

Post-1900 Succession—There has been relatively little human activity in the vast expanse of the arctic tundra (Heinselman 1981). Most activity has been since the late 1960s with oil and gas exploration and the construction of pipelines. Disturbance to tundra communities has been mostly in the form of cut-lines

(or seismic lines), winter roads, air strips, and fire (Bliss and Wein 1971). Continuing investigation into the effect of these anthropogenic disturbances has resulted in the use of technologies that have a less deleterious impact on plant communities of the tundra.

Management Considerations—Efforts to contain or stop the spread of fire in the tundra produce more drastic long-term effects than the fire itself (Brown 1971; Viereck and Schandelmeier 1980). Construction of firelines with bulldozers strips away all insulating moss and peat layers and exposes bare mineral soil. This allows the summer heat to penetrate directly into the frozen ground, which in turn increases the depth of the active layer under the fireguards compared to under burned areas. This causes a more rapid and greater degree of subsidence under the firelines than under the burned areas due to the melting of ground ice (Brown 1971), erosion and gully formation (Brown 1983).

Chapter 4: Fire in Eastern Ecosystems

Prior to Euro-American settlement, fire was a ubiquitous force across most of the Eastern United States. Fire regimes spanned a time-scale from chronic to centuries. Fire severity varied from benign to extreme (fig. 1-2). Today, fire is still a major force on the landscape. In some ecosystems fire stabilizes succession at a particular sere, while in others, succession is set back to pioneer species. The wide range in fire regimes coupled with elevation and moisture gradients produce a myriad of plant communities that continually change over time in both stature and composition, although it is not uncommon for the major species to remain dominant. Discussion is primarily about major vegetation types, for example, oak-hickory. However, some minor types such as spruce-fir and Table Mountain pine are also covered. Vegetation types are discussed under the most representative fire regime type, recognizing that some vegetation types overlap two fire regime types (table 4-1).

Understory Fire Regimes

Major Vegetation Types

The presettlement understory fire regime (overstory survival typically exceeds 80 percent) primarily applies to southern pine and oak-hickory forests

comprised of pine and pine-oak associations such as Kuchler's southern mixed forest, oak-hickory-pine, Northeast oak-pine types, and oak-hickory associations. Kuchler potential natural vegetation classes are listed by fire regime types in table 4-1 and cross-referenced to FRES ecosystems and Society of American Foresters cover types.

The extent of the various forest types at the time of Euro-American colonization is difficult to reconstruct. Considering old survey corner trees, Plummer (1975) concluded that pine and post oak predominated in the Georgia Piedmont. Based on soils, Nelson (1957) concluded that 40 percent of the Piedmont was in hardwoods, 45 percent was hardwood with varying degrees of pine, and 15 percent was predominantly pine. Nomenclature used by early naturalists was often ambiguous including different names for the same species, or use of a species name to group several species together such as the use of the term short-leaf pine to differentiate all short-leaved pines from longleaf pine. Furthermore, earlier works estimated that 80 percent of this region had been cleared at some point in time (Nelson 1957). Hamel and Buckner (1998) described the "original southern forest" at three periods and concluded that no specific period represents the "true" original condition of the southern forest because it has been shaped by humans for millennia.

Table 4-1—Occurrence and frequency of presettlement fire regime types by Forest and Range Environmental Study (FRES) ecosystems, Kuchler potential natural vegetation classes (1975 map codes), and Society of American Foresters (SAF) cover types. Occurrence is an approximation of the proportion of a vegetation class represented by a fire regime type. Frequency is shown as fire interval classes defined by Hardy and others (1998) followed by a range in fire intervals where data are sufficient. The range is based on study data with extreme values disregarded. The vegetation classifications are aligned to show equivalents; however, some corresponding Kuchler and SAF types may not be shown.

The Southern mixed hardwood forest occupies the Atlantic and Gulf Coastal Plains and is often classified as deciduous broadleaved forest even though it includes pine-hardwood and broadleaved evergreen types. Southern pines are the predominant overstory species. The potential hardwood climax, however, was probably only reached on sites with a geomorphologic position or hydrologic condition that protects such sites from the chronic fire regime that characterizes this region. Southern mixed hardwood forests were confined to narrow strips between floodplain forests and uphill longleaf pine forests before Euro-American colonization (Batista and Platt 1997). Some authors placed the former longleaf pine forests in this forest type, but this seems illogical where time since disturbance, primarily by hurricanes and fire, and the elevation gradient (measured in inches) determine plant community composition. Embedded within this overall forest type are numerous other ecosystems such as nonalluvial depressional wetlands, including Carolina bays, limesinks, cypress ponds and savannas, gum ponds, bay swamps, pitcherplant bogs, shrub bogs, and spring seeps. Water stands in these depressions during at least part of the growing season, but they also dry allowing fire to enter from adjacent upland plant communities (Kirkman and others 1998; Wharton 1977). These fires regulate numerous processes needed to maintain these communities (Christensen 1977; Wade and others 1980; Wright and Heinzelman 1973). Periodic fire also knocks back the wall of hardwoods that continually invades adjacent upland sites (Barrett and Downs 1943; Chaiken 1949; Chapman 1947; Harcombe and others 1993; Heyward 1939; Long 1888; Oosting 1942; Platt and Schwartz 1990; Wahlenberg 1949; Wells 1928). As the time span between fires increases, the stature of the ever-present hardwoods also increases, shading out the herbaceous groundcover, thereby breaking up its continuity and ability to support spread of fire; this allows the hardwoods to further expand until they eventually dominate the site (fig. 4-1). Tansley (1935) recognized this situation and classified Southeastern pine forest as a disturbance-dependent pyrogenic stable type. Wilhelm (1991) extended this thinking to the Central Hardwoods Region and questions the whole concept of succession and climax vegetation in the Midwest.

Over three dozen oaks and almost two dozen hickories form a myriad of potential overstory plant communities that comprise the oak-hickory forest (fig. 4-2). We define it as all stands in which oaks and hickories, singly or in combination, compose at least 50 percent of the dominant trees (J. A. Barrett 1994; Braun 1950). This forest type includes the oak-hickory-pine forest of the mid-Atlantic States, the Appalachian oak forest, the Northeast oak-hickory-pine forest, and stands within the western mesophytic and mixed mesophytic

forest regions where oaks and hickories comprise a majority of the dominant trees. Such stands occur primarily on average to dry upland sites, although they can be found on moist upland sites as well, depending upon past disturbance history. Where other hardwood species dominate within the western and mixed mesophytic forest regions, they are discussed as mixed fire regime types.

Fire Regime Characteristics

Southern Pine Forests—The regional climate is characterized by long, hot growing seasons, abundant rain punctuated by occasional multiyear droughts, and the most frequent wind and lightning (Komarek 1964) storms in North America. Natural disturbance events such as microbursts, tornadoes, and hurricanes can significantly impact forested lands at several scales and often set the stage for more intense fires (Myers and Van Lear 1997). Lightning becomes increasingly common as one moves from north to south. Although the number of lightning fires peaks in June and July, the vast majority of acreage now burns in May and June in Florida (Robbins and Myers 1992) and southern Georgia, before the summer thunderstorm pattern becomes fully entrenched; this probably was the historic pattern as well.

The few remaining old-growth southern pine forest relics are too small to experience natural fire regimes, and neither dendrochronology nor palynology can be used to determine fire history in this region (Landers 1991). Thus, historical southern pine fire regimes must be inferred from interpretation of old records, field observations, experimental studies, and species traits. Frost's (1998) generalized map of pre-Euro-American settlement fire frequency for the Southern United States summarizes current thinking and shows that all forest types mentioned above had a fire-return interval of less than 13 years except pond pine pocosins in North Carolina.

Before Euro-American settlement, some fires were undoubtedly far ranging because they were associated with dry frontal passages. Growing season fires during severe drought years can burn for weeks or months, particularly in organic soils that underlie the deeper depressional wetlands, before being extinguished by rain and a rising water table (Cypert 1961, 1973). Such fires make frequent forays into adjacent upland communities. Most fires were, however, probably limited in extent, at least once the summer convective weather pattern set in. Nighttime humidities near 100 percent are the norm during the summer; and such humid, calm conditions tend to extinguish fires in light fuels. The pattern of occasional high-intensity, wind-driven fires and severe drought fires was superimposed on the chronic lightning and Native American fire regime

Figure 4-1—Fifty years of fire exclusion in an old-growth longleaf pine stand, Flomaton, Alabama. Photo by John Kush, 1994.

Figure 4-2—The combined distribution of the Oak-Hickory Forest Region, Mixed Mesophytic Forest Region, and Appalachian Oak Forest Region (Kuchler Types 100, 103, and 104) as depicted by Martin and others (1993).

creating the open woodlands referred to by early Euro-American explorers (Barden 1997; Landers and others 1990; Olson 1996) (fig. 4-3). The journals of many of these explorers also mention numerous smoke columns and extensive smoke and haze often lasting for days.

Native Americans used fire extensively to shape the vegetative mosaic for thousands of years, and for the past 400 or more years Euro-Americans have subjected these same lands to varying degrees of fire use and abuse, including the exclusion of fire. Whether human ignitions substantially increased the total acres treated by fire is uncertain, but based on the sheer number of artifacts left behind, accounts by early white explorers, and studies of depopulation ratios following disease (Dobyns 1966; Jacobs 1974), Native American populations must have been much larger than is generally recognized. According to Kennedy (1994), the population of Cahokia in central Illinois was greater than that of London in the 13th century. Native American-induced changes include the fact that they ignited fires throughout the year, but before their influence, many sites burned more frequently by fires confined to the spring and summer thunderstorm season (Martin and Sapsis 1992). A slight shift toward reduced fire intensity and severity took place. Growing-season fires tend to be patchier than dormant-season fires because of different weather patterns and

Figure 4-3—Pine flatwoods near Tallahassee, Florida, around 1900. Note open understory. Florida Department of Environmental Protection archives.

greater variation in fine-fuel moisture once greenup occurs.

Komarek (1982) pointed out that it is difficult to understand the practice of prescribed fire in the South without an appreciation of Southern history. It is also a prerequisite to realizing the tremendous impact humans have had in shaping the present vegetative mosaic. For example, prior to the Civil War, over 75 percent of the white population were pastoral herds-men (Owsley 1945) who came from the British Isles, Spain, and France where fire was an integral part of their livelihood. They brought this practice with them, blended their knowledge with that of the Native Americans they displaced, and aggressively expanded the use and frequency of fire throughout the South. A circa 1731 North Carolina law required the annual burning of all pastures and rangelands every March (Carrier and Hardison 1976). Eldredge (1911) described the turn-of-the-century fire situation in north Florida as follows:

...the turpentine operator burns his woods and all other neighboring woods during the winter months, generally in December, January, or February. The cattleman sets fire during March, April, and May to such areas as the turpentine operator has left unburned. During the summer there are almost daily severe thunderstorms, and many forest fires are started by lightning. In the dry fall months hunters set fire to such "rough" places as may harbor game. It is only by chance that any area of unenclosed land escapes burning at least once in two years.

There is little doubt that this pattern was typical throughout the region, although not everyone was in agreement with this ubiquitous use of fire. The debate regarding the benefits of intentional burning versus fire exclusion has been ongoing for more than 100 years as attested to by the following quote from the 1875 Atlanta Constitution (Blocker 1875).

I have seen an article in the Early County News of June 12th, copied from the Columbus Sun condemning the burning of woods, but the writer is very badly mistaken in his views on the subject. I think there has been a great deal more injury from not burning the woods at a proper time, and when in proper condition, than has ever been done by burning; for fire will accidentally get in some time, and often when it is very dry, and do a great deal of injury.

Although some early Federal foresters thought fire was universally bad (Schwarz 1907), others disagreed. Chiefs of the United States Forest Service Gifford Pinchot (1899) and Henry Graves (1910), Supervisor of the Florida National Forests I.F. Eldredge (1911), as well as university researchers Gifford (1908), Bryant (1909), and Chapman (1912) recognized the invariable result of attempted fire exclusion and advocated the use of prescribed burning in Southern pines as a hazard reduction measure. However, with passage of the Clarke-McNary Act in 1924, which offered the States Federal funding for fire suppression, thinking within the Forest Service reversed itself, the use of fire was condemned (Demmon 1929), and the Dixie Crusaders crisscrossed the Deep South preaching the evils of woods burning. An excellent account of the methods used to force compliance with this new fire exclusion policy is given by Schiff (1962).

With attempted fire exclusion, dead fuels accumulated on the forest floor and a needle-draped understory of highly flammable shrubs such as saw palmetto, gallberry, and wax myrtle developed within 5 or 6 years on all but xeric sites. Given this receptive fuel bed and human and natural ignition sources, wildfire occurrence remained high. At first, these fires were easy to extinguish, but as fuels accumulated on unburned areas, fires became increasingly difficult to suppress, and the probability of catastrophic,

high-intensity fire increased. Often, the postfire outcome was atypical successional pathways with concomitant declines in flora and fauna (fig. 4-4).

Many of these ecosystems can still be restored with the judicious reintroduction of fire (fig. 4-5), sometimes in combination with other chemical and mechanical methods, because the long association between fire and Southern vegetation has evolved species traits (table 2-1) that favor them in fire-prone ecosystems (Christensen 1977; Landers 1991). Providing a certain threshold limit has not been reached, the natural resiliency within these systems allows them to recover (Vogl 1976). However, once this threshold limit has been exceeded, nature can no longer rectify the situation. Thus, many components of the original ecosystem cannot survive long periods without fire (Garren 1943).

Most students of fire history agree that typical longleaf pine sites burned every 1 to 4 years prior to the arrival of Europeans, and then every 1 to 3 years until aggressive fire suppression activities began in the 1920s and 1930s (Landers 1991; Landers and others 1990). As typical upland sites grade toward mesic (wet) or xeric (dry and thus low rates of fuel accumulation), fire frequency decreases. Loblolly, slash, and pond pines were historically confined to

wetter sites (Monk 1968) where a 3 to 4 year fire-free interval allowed saplings to become large enough to withstand low intensity fire. In developing a definition for old-growth wet-pine forests, Harms (1996) emphasized the fact that fire is necessary to establish and maintain these ecosystems. The historic shortleaf pine fire return interval is thought to have ranged from about 2 to 6 years on fertile, lower elevation sites to 6 to 15 years on drier, nutrient-poor sites where fuels take longer to accumulate. Annual burning was extensively practiced throughout the shortleaf pine region (Mattoon 1915).

Fires in the depressional wetlands embedded in the understory fire regime types are typically stand-replacement. Wharton (1977) gives fire cycles for these types as follows: 3 to 9 years in herb bogs and high-diversity shrub bogs (including pocosins); 20 to 30 years in many cypress ponds, gum ponds and bog swamp; 20 to 50 years in low diversity (titi) shrub bogs; and 50 to 150 years in some cypress ponds and bay swamps.

Perturbations to these chronic low-intensity Southern pine fire regimes occurred in the form of episodic (often catastrophic) events such as blowdowns (fig. 4-6) and drought, which were precursors to fires of much higher intensity and severity (Myers and Van Lear

Figure 4-4—The forest floor accumulated from decades of fire exclusion completely consumed after an extreme drought-year fire on Myakka River State Park, Florida. 1997). Explosive increases in southern pine beetle (*Ips* spp. and *Dendroctonus frontalis*) populations and subsequent pine mortality often either preceded or followed these fires. In nature, such infrequent events are often controlling factors that have profound effects limiting vegetative development past a certain point so that succession is a cyclic phenomenon (Vogl 1976).

Intentional use of fire to manage vegetation again became commonplace after World War II. Besides rough reduction, vast acreages were burned to: (1) improve native range (Halls and others 1952, 1964; Hilmon and Hughes 1965a; Lewis 1964; Shepherd and others 1951), (2) control the relentless hardwood invasion into pine stands (Brender and Cooper 1968; Chaiken 1952; Ferguson 1957; Harrington and Stephenson 1955; Lotti 1955), and (3) manipulate wildlife habitat to favor herbs and forbs and replace unpalatable out-of-reach woody understory crowns with succulent, nutritious sprouts (Brennan and others 1998; Harlow and Van Lear 1981, 1987; Harris 1978; Wood 1982).

During the 1980s, an estimated 4 million acres (10 million ha) of forest land and 4 million acres of range and agricultural land were treated with prescribed fire each year in the Southern United States (Wade and Lunsford 1989). Prescribed fire is used by Southern resource managers to meet widely varying objectives: restoration and maintenance of ecosystems, reduction of hazardous fuels, reduction of wildfire size and suppression costs, reduction of firefighter risks, preparation of seedbeds and planting sites, facilitation of harvesting (fiber, plants, game animals, insects, and earthworms), enhancement of wildlife habitat, range improvement, control of insects and diseases, thinning overly dense stands, maintenance of scenic vistas, promotion of showy herbaceous species, manipulation of understory structure and composition, creating a safer environment for woods workers and equipment operators, favoring plant and animal species of special concern, eradication of vermin, control of exotic species, stimulation of fruit and fiber production, disposal of crop residues, and recycling of nutrients. The majority of treated acreage is for hazard reduction, wildlife habitat improvement, and range management. Nearly 2 million acres (0.8 million ha) of rangeland are burned annually in Florida alone. An increasing area is burned each year to maintain the function of fire in ecosystems, particularly on State and Federal lands. Today, prescribed fire is used to treat over 6 million acres annually, which is only a small fraction of the land that once supported the vast Southern pine forests.

Oak-Hickory Forests—The fire regime of the oak-hickory forest has varied spatially and temporally because of changing cultural influences before, during, and after Euro-American settlement. Before such

influence, the fire regime for oak-hickory forests was dictated by the activity of Native Americans because they were the primary ignition source (Abrams 1992; Buckner 1983; Denevan 1992; Pyne 1997). Native Americans in the Central Hardwoods Region (Delcourt and Delcourt 1997, 1998; Olson 1996), the Appalachians and Piedmont (Van Lear and Johnson 1983), and the Northeast (Buell and others 1954; Day 1953) commonly used fire for numerous reasons throughout the year. Surface fires predominated and burned over large areas; only natural barriers or unfavorable weather stopped them. Hough (1877) thought the “oak openings,” “barrens,” and prairies east of the Mississippi resulted from Native American use of fire to promote grass growth and attract game. He stated, “Scarcely a year passes without the occurrence of fires of sufficient extent to attract public notice.” Numerous authors (DeViro 1991; Patterson and Sassamen 1988; Stewart 1951, 1963; Van Lear and Waldrop 1989) have discussed the vast extent to which Native Americans used fire. One historian (Russell 1983) agreed that fire frequency was greater near camps and villages than would be expected by lightning, but found no strong evidence that Native Americans burned large areas in the Northeast.

Lightning fires are uncommon in many of these regions because thunderstorms occur primarily during the growing season, usually accompanied by rain (Barden and Woods 1974; Ruffner and Abrams 1998). However, lightning fires regularly occur in some areas such as the Piedmont of North Carolina (Barden 2000).

Presettlement fire frequencies are not known. Delcourt and Delcourt (1997, 1998) believe they varied considerably depending on closeness to Native American habitation. Other references point out that Native Americans maintained an extensive trail system throughout the East that was kept open with fire. Euro-American explorers reported many areas treated with annual and biennial fires (Barden 1997; Buckner 1983; Day 1953). Dendrochronological studies, which give conservative estimates, suggest fire return intervals of 7 to 14 years in the mid-Atlantic and Ozark regions (Buell and others 1954; Guyette and Day 1997). Cutter and Guyette (1994) reported a fire-return-interval of 2.8 years during 1740 to 1850 on a ridgetop in the Mark Twain National Forest. Presettlement fires in southern New England generally occurred during the spring and summer (Bromley 1935; Christianson 1969). Brown (1960) believes the prevalence of oak in Rhode Island is the result of a long history of fire. The fire regime was probably more pronounced in Southern areas than in Northern areas due to more favorable climatic conditions for ignition and spread, greater populations of Native Americans, and vegetation more conducive to burning.

The frequency and extent of Indian burning decreased substantially after white contact, which introduced new diseases and decimated their population by 90 percent or more over the next 100 to 150 years (Denevan 1992; Dobyns 1983; MacCleery 1993). As a result grasslands, savannas, and woodlands succeeded to closed forest (Buckner 1983; Denevan 1992; Dobyns 1983; MacCleery 1993, 1995; Pyne 1997) (fig. 4-7). Subsequent settlement of the oak-hickory forests by Euro-Americans, who used fire for many of the same reasons as the Native Americans, increased the frequency and extent of burning (Abrams 1992; Pyne 1997; Van Lear and Waldrop 1989). Fire return intervals were shortened to 2 to 10 years with many sites burning annually (Cutter and Guyette 1994; Guyette and Day 1997; Holmes 1911; Sutherland and others 1995; Sutherland 1997). For example, the barrens of Pennsylvania and Maryland were burned annually at least through 1731 (Tyndall 1992).

Presently, the fire regime of oak-hickory forests is characterized by infrequent, low-intensity surface fires that occur during the spring and fall. They are caused almost exclusively by humans, and burn small areas (Pyne and others 1996). Lightning is a minor ignition source (Barden and Woods 1974; Ruffner and Abrams 1998). Fire return intervals have lengthened from a few years to several millennia (Harmon 1982), the longest fire-free intervals in the history of the Central Hardwoods Region (Ladd 1991).

Fuels and Fire Behavior

Southern Pine Forests—Most studies show that the amount of dead understory and forest floor material less than 3 inches in diameter varies widely by site, overstory basal area, and time since last fire (table 4-2). Live and dead accumulated fuel loadings in slash pine and longleaf pine stands can increase five to ten fold from 1 year after a fire to 20 years later. In mature Southern pine forests on the Atlantic Coastal Plain, stand average forest floor fuel loadings ranged from about 1.5 tons/acre (3.4 t/ha) under an annual dormant-season fire regime to 13 tons/acre (29.1 t/ha) after 40 years (Boyer and Fahnestock 1966; Bruce 1951; Geiger 1967; McNab and others 1978; Southern Forest Fire Laboratory Staff 1976; Williston 1965). Live groundcover and understory fuels less than 1 inch in diameter ranged from about 0.75 tons/acre (1.68 t/ha) with annual burns, to over 11 tons/acre (25 t/ha) after 25 years (table 4-3). Halls (1955) reported that grass production varied from about 300 lb/acre (336 kg/ha) under dense longleaf-slash pine stands to 1,000 lb/acre (1,120 kg/ha) on open forest rangelands. Equations for predicting forest floor and understory fuel weights from stand factors and age of rough were developed by Williston (1965), Geiger (1967), and McNab and others (1978) that explain 70, 80, and 86 percent of the variation in fuel weight, respectively.

^aApplies to stands with and without understory vegetation (McNabb and Edwards 1976).

Fuel loading trends are similar on Piedmont sites for shortleaf pine and mixed pine-hardwood (Metz 1954); shortleaf pine (Crosby 1961; Johansen and others 1981); loblolly pine (Southern Forest Fire Laboratory Staff 1976); loblolly, shortleaf, and Virginia pines (Metz and others 1970); loblolly pine and groundcover (Brender and Williams 1976); longleaf, loblolly, and shortleaf pines, mixed pine-hardwood, and wiregrass (Albrecht and Mattson 1977). Fuel loadings were highest in loblolly and longleaf pine stands, and appreciably lighter in shortleaf and Virginia pine stands. Fuel loadings in shortleaf and mixed shortleaf pine-hardwood stands in the mountains of North Carolina

were substantially heavier than those on the Piedmont, partly because of a heavier understory component (Albrecht and Mattson 1977). Prediction equations that explain 80 percent of the variation in forest floor loadings and 90 percent for the groundcover were developed by Brender and Williams (1976).

Photo series publications are available showing fuels and estimated loadings for various Southern pine types (Lynch and Horton 1983; Ottmar and Vihnanek, in press; Sanders and Van Lear 1988; Scholl and Waldrop 1999; Wade and others 1993).

Resource managers usually prescribe conditions that limit fuel consumption to 1 to 3 tons/acre (2.2 to 6.7 t/ha)

Table 4-3—Understory vegetative loading (tons/acre dry weight) in the palmetto-gallberry type related to age of rough and understory height (Southern Forest Fire Laboratory Staff 1976).

^aA situation not likely to be found in nature.

during passage of the flame front (fig. 4-8). Residual combustion can more than double these values, especially under drought conditions, or 5 to 6 years after a major disturbance when large down woody fuels have become punky. Percent litter reduction and energy release from backfires in palmetto-gallberry can be predicted given the weight and moisture content of the total litter layer (Hough 1968). Available fuel can be estimated knowing total fuel loading and moisture content (Hough 1978).

Annual and biennial prescribed headfires on the Atlantic and Gulf Coastal Plains typically move through the herbaceous groundcover with fireline intensities less than 500 Btu/ft/s (144 kW/m). Dead woody stems killed in the previous fire are often still standing and can substantially contribute to fire behavior. Where the canopy is open, midflame wind speeds often approach 4 to 5 mph. Short distance spotting up to 10 to 15 feet (3 to 4.6 m) is fairly common in herbaceous fuels such as wiregrass, broomsedge, and switchcane, especially as relative humidity drops below 35 percent. Rate of spread is always less than midflame windspeed on level ground (ignoring spotting) and typically falls between 200 and 1,500 feet/hour (60 to 460 m/hr) for heading fires and less than 150 feet/hour (46 m/hr) in backing fires. Short runs where headfire rate-of-spread is more than doubled are not infrequent under gusty winds. Headfire flame length can vary widely, from

less than 0.5 feet (15 cm) to over 10 feet (3 m) in 2 year palmetto-gallberry roughs depending primarily upon windspeed, fine-fuel moisture content, fuelbed depth and porosity, and ignition pattern. Where the objective is to topkill hardwoods, backfires are often utilized because they concentrate released heat energy near the ground (Lindenmuth and Byram 1948).

In uniform 4 year old palmetto-gallberry roughs, headfire spread rates can exceed 0.5 mph (0.8 km/hr) with flame lengths in excess of 20 feet (6 m) and fireline intensities of 2,000 Btu/ft/s (578 kW/m) under "good" burning conditions and Lavdas Dispersion Index (Lavdas 1986) values above 70. Firebrands consisting primarily of dead palmetto fronds are common and often ignite spot fires 10 to 30 feet (3 to 9 m) ahead of the fire front as relative humidities drop below 35 percent. More detailed descriptions of fuels and fire behavior can be found elsewhere (Cheney and Gould 1997; Hough and Albini 1978; Johansen 1987; Wade 1995; Wade and Lunsford 1989; Wade and others 1993).

Oak-Hickory Forests—Leaf litter is the primary fuel that sustains fire. Loading and thickness vary depending on site, stand age, and time of year (Albrecht and Mattson 1977; Blow 1955; Crosby and Loomis 1974; Kucera 1952; Loomis 1975; Metz 1954). Hardwood leaves tend to cup and hold water after a rain, although the leaves of some species of oak tend to curl

Figure 4-8—Dormant-season prescribed fire backing through 12-year palmetto-gallberry rough in Collier County, Florida. Photo by Dale Wade, 1977.

and dry quickly in comparison to other hardwoods, allowing fire to run through oak litter when other hardwood fuel types are too wet to burn. Fuel loadings in like stands on comparable sites vary little longitudinally, but increase northward because decreasing mean temperatures slow decomposition. Litter loading and depth are greatest immediately after leaf fall in the autumn and decline until the following autumn.

Most stands have litter loadings ranging from 1 to 4 tons/acre (2.5 to 9.9 t/ha) and depths of 1 to 5 inches (2.5 to 12.7 cm), depending on time of year. For example, the forest floor under a 150 year old hickory stand (91 sq. feet basal area) on the Piedmont of South Carolina averaged 3.1 tons/acre (7.0 t/ha) and 4.1 tons/acre (9.2 t/ha) under a nearby 50 year old oak stand (62 sq. feet basal area) (Metz 1954). Annual litter production in fully stocked oak stands in Missouri averaged 2.1 tons/acre (4.7 t/ha) (Loomis 1975). The total forest floor loading (exclusive of material larger than 0.5 inch diameter) in the same stands averaged 8.3 tons/acre (18.6 t/ha), but 6.4 tons/acre (14.3 t/ha) in a younger stand (Crosby and Loomis 1974). In hardwood stands of several Northeastern States, the L, F, and H layers averaged 1.0, 3.3, and 5.9 tons/acre (2.2, 7.4, and 13.2 t/ha), respectively (Mader and others 1977). Generally duff contributes little to fire spread but does influence fire effects, especially during droughts.

Savannas typically contained grasses that were 3 to 6 feet (1 to 2 m) high according to early explorers (Barden 1997; Buckner 1983; Denevan 1992). Based on grass height, loadings may have ranged from 2 to 5 tons/acre (4 to 11 t/ha). After decades, fire exclusion allows the mid-story forest canopy to close, and herbaceous fuels are shaded out and become relatively unimportant as a fire carrier.

Small woody fuels are often abundant in young stands originating after a major disturbance. Woody fuels are less abundant in mid-successional and mature stands and increase in old-growth stands due to accumulation of large woody material. When present, ericaceous shrubs such as mountain laurel and rhododendron can burn with extreme fire behavior resulting in a mixed-severity or stand-replacement fire (Waldrop and Brose 1999). Many of the firefighter fatalities in hardwood forests have occurred because of the explosive nature of these fuels.

Postfire Plant Communities

Current and pre-Euro-American settlement vegetation types may have little in common because most of the original vegetation was either logged or cleared for agriculture prior to World War I. Many Eastern States currently have more acres in forest than they did 150 years ago.

Longleaf pine

Vegetation Dynamics—The longleaf pine ecosystem is distinguished by open pine forests, woodlands, and savannas. It is found on the Coastal Plain from Virginia to Texas, and in the Piedmont and Appalachian Highland (both Blue Ridge and Valley) physiographic provinces of Alabama and Georgia (Boyer 1990a; Wahlenberg 1946) (fig. 4-9). Longleaf pine tolerates a wide range of sites from wet, boggy flatwoods underlain with tight clays across xeric, deep-sand hills to thin stony soils on southerly-facing mountain slopes. Surface soils are typically acidic, tend to dry quickly after precipitation (especially the Quartzipsamments), and are characterized by a lack of organic matter and low fertility (Landers and Wade 1994). Vegetation that dominates these oligotrophic sites is resistant to biological decomposition because of its high C to N ratio but is amenable to thermal decomposition (Hon Tak Mak 1989). Key plants exhibit pronounced fire tolerance, are long lived, and are efficient at gathering nutrients and water, which reinforces their dominance and restricts the rate and spatial scale of vegetation change including species turnover. A feedback loop thus exists that includes climate, key plants, and vast expanses that are quick drying and topographically susceptible to disturbance; these factors all interact to maintain a chronic fire regime. Recurrent fire is

Figure 4-9—The longleaf pine forest region (after Stout and Marion 1993). The shaded area shows the distribution of longleaf pine (Critchfield and Little 1966). A dotted line indicates the landward extent of wiregrass and the western and northern limits of its distribution. A dashed line indicates the northern limit of saw palmetto.

crucial to perpetuation of longleaf pine ecosystems as noted by Andrews (1917) and many others since. These ecosystems persist and maintain their diversity because of, rather than in spite of, constant disturbance and infertile soils (Christensen 1993a; Landers and Wade 1994; Landers and others 1995; Wells and Shunk 1931).

The flora and fauna that dominate this ecosystem are those with well-developed adaptations to chronic fire. This fire regime maintained a two-tiered structure comprising an open longleaf pine overstory and an unusually diverse groundcover dominated by bunchgrasses (fig. 4-3). According to Peet and Allard (1993), this is one of the most species-rich ecosystems found outside the tropics. Overviews of the plant and animal communities that form this ecosystem can be found in Bridges and Orzell (1989), Harcombe and others (1993), Myers and Ewel (1990), Platt and Rathbun (1993), Skeen and others (1993), Stout and Marion (1993), and Ware and others (1993).

Longleaf pine has numerous traits that make it highly tolerant of fire (table 2-1). After an initial grass stage it puts on a growth spurt (called bolting) that quickly gets its terminal bud above potential flames. Bark thickens rapidly during the first year of height growth and protects stems from light surface fires. The large buds have a high heat capacity and are protected by a surrounding sheaf of long needles.

Fire results in small-scale temporary changes in light, water, nutrients, and space along the elevation-moisture gradient. These sites are further modified by frequent treefalls resulting from lightning, beetle activity, and faunal excavations primarily by the gopher tortoise (*Gopherus polyphemus*) and pocket gopher (*Geomys* spp.). Hermann (1993) described the importance of these microsites. Strong wind events and hydrologic extremes introduce ephemeral resource features over much broader areas. Thus a wide array of habitats is continuously available to vegetative change, which allows opportunistic plant species to coexist with more permanent ones. Without frequent fire, woody species overtop the herbs, strongly acidic pine needles accumulate forming a duff layer, nutrient dynamics change, and soil fertility increases, which all favor extrinsic species at the expense of endemic residents. About 191 taxa of vascular plants associated with the longleaf-bunchgrass system are threatened and endangered (Walker 1993), primarily because: (1) habitat has been paved over, (2) intensive site preparation associated with row crops took place prior to agricultural abandonment or when directly converting to other pine species, (3) frequent fire has been excluded, and (4) water tables are dropping. The fauna also contains many endemics that are either Federally or State listed as threatened or endangered.

Natural stands of longleaf pine may average from just one or two canopy trees per acre on extremely dry,

deep sand ridges to over 150 per acre on good mesic sites (Schwarz 1907). Glitzenstein and others (1995) found that when burned on a 2 year cycle, longleaf pine canopy tree damage is primarily related to variation in fire intensity rather than month of application. Forest openings resulting from death of overstory trees are maintained by frequent fire until eventually colonized by shade-intolerant longleaf pine whose seed require a mineral soil seedbed. Germination takes place as soon after seed fall as moisture becomes adequate. The seedlings can withstand low-intensity fire the following growing season; fire is sometimes applied at this time to destroy seedlings of competing species to increase the longleaf pine component. If the longleaf pines are not yet fully established, they are often topkilled, but sometimes resprout (Grace and Platt 1995). With extended periods of fire exclusion, hardwoods dominate forest openings (Gilliam and Platt 1999).

Longleaf pine seedlings undergo a grass stage lasting several years where no height growth occurs, but a taproot develops and the root collar thickens. During the grass stage, seedlings are often infected by a fungal disease called brownspot needle blight (*Scirrhia acicola*), which weakens the plants so they eventually die. Fire controls this disease by consuming the infected needles and stimulating the seedlings to initiate height growth, perhaps due to the release of nutrients (Christensen 1977).

The bunchgrass and longleaf pine fuel mixture can burn within hours of a soaking rain so that an early afternoon lightning strike in a dead snag often smolders in the accumulation of dead bark, litter, and branches at its base resulting in a fire later that day or the next day. Thus the longleaf pine type transforms lightning strikes into fires, which then spread through the highly flammable herbaceous groundcover and needle litter throughout its ecosystem (Platt and others 1988b) and into neighboring ecosystems as well. It is not surprising that lightning is the leading cause of mortality of longleaf pine (Komarek 1968; Platt and others 1988b). Kirkman and others (1998) characterized the ecotone between upland longleaf pine and seasonally ponded wetlands. The hydric soil boundary was consistently upslope from the vegetation boundary, which led them to conclude that the abrupt changes in vegetation were likely related to fire periodicity.

Southern pines have been exploited since Euro-American colonization. During the first two decades of the 20th century, the remainder of the "original" Southern pine forest was heavily cutover, and then indiscriminately burned at least every spring to promote forage for free-ranging cattle (Stoddard 1962). These fires eliminated all pine regeneration except for grass-stage longleaf pine. However, reforestation of this species was prohibited by lack of an adequate longleaf pine seed source (its seed is too heavy to be effectively wind disseminated) and feral pigs that

uprooted seedlings (Frost 1993). Fire exclusion was seen as the only choice that would allow reforestation of these lands. This policy allowed the aggressive, less fire-tolerant loblolly and slash pines to move from the more mesic sites where they had been confined under the previous chronic fire regime (Landers and others 1995). The result was a dramatic shift in the makeup of the emerging forest. Extensive type conversion by the pulp and paper industry to genetically groomed loblolly and slash pines with faster juvenile growth than longleaf pine further exacerbated these species composition shifts. The longleaf pine ecosystem, which once dominated about 75 million acres (30 million ha) (Chapman 1932), has been extirpated from over 95 percent of its historical area (Frost 1993; Outcalt and Sheffield 1996) and is listed as critically endangered by Noss and others (1995).

Associated Vegetation—Conifer associates of longleaf pine include loblolly pine, slash pine, and pond pine on wetter sites and shortleaf pine, Virginia pine, and sand pine on drier sites depending upon the fire return interval and fireline intensity, particularly during the juvenile growth stage. The groundcover comprises primarily bunchgrasses such as wiregrass along the Atlantic seaboard (Lemon 1949; Lewis and Hart 1972; Lewis and Harshbarger 1976) and little bluestem and slender bluestem from central Alabama westward (Grelen and Duvall 1966). Common woody understory species include saw palmetto, gallberry, and wax myrtle. The live foliage of all three shrubs is

unexpectedly flammable because of the release of volatiles, which promote fire spread and higher fireline intensities. Numerous studies describe the relationship between fire and various longleaf pine-dominated plant assemblages (Harcombe and others 1993; Huffman and Werner 2000; Landers 1991; Lewis and Hart 1972; Peet and Allard 1993; Wells and Shunk 1931; Yahr and others 2000), between fire and indigenous fauna (Brennan and others 1998; Engstrom 1993; Folkerts and others 1993; Guyer and Bailey 1993; Jackson 1989), and between both flora and fauna (Stout and Marion 1993; Ware and others 1993; Weigl and others 1989).

Under natural fire regimes, dry-site oaks are generally the only hardwood associates to reach the midstory. Common species include turkey oak, bluejack oak, blackjack oak, and sand post oak. Based on current information, Rebertus and others (1993) hypothesized that both longleaf pine and these upland oaks are fire dependent and that longleaf pine becomes more important relative to the oaks as fires become more frequent and occur during the early growing season. Greenberg and Simons (1999) presented evidence showing oaks have been an integral midstory component of many high pine sites (Myers and Ewel 1990) in Florida for at least several centuries.

Disrupted fire regimes result in an invasion of other hardwoods such as sweetgum, oaks, hickories, common persimmon, and southern magnolia (Daubenmire 1990; Gilliam and Platt 1999) (fig. 4-10). These

Figure 4-10—Hardwoods are confined to the understory with annual dormant-season fire (on left) and form a midstory with fire exclusion (on right), Okefenokee National Wildlife Refuge. Photo by Ron Phernetton, 1992.

hardwoods form a midstory and prevent the shade-intolerant longleaf pine from reestablishing. Many of these hardwoods are somewhat resistant to low-intensity fires when mature (Blaisdell and others 1974). Understory trees are usually top-killed, but their rootstocks are able to withstand all but annual growing-season fires (Waldrop and others 1987). Where oaks form a midstory because of fire exclusion, Glitzenstein and others (1995) found that late spring and early summer burns increased oak topkill. Where variations in microsite result in patchy growing-season burns, hardwoods occasionally reach the overstory, but not in sufficient numbers to assert dominance. For example, Plummer (1975) determined from old records that the two most common hardwood associates of the 18th century longleaf pine forest in southwestern Georgia were oak and hickory, which comprised 1.0 and 0.5 percent of the stems, respectively, and longleaf pine 91 percent. The influx of exotics that are promoted by fire such as cogongrass (Lippincott 1997), Japanese climbing fern, and melaleuca (Wade 1981; Wade and others 1980) will be an increasingly serious problem.

Management Considerations—Fragmentation of the original landscape by conversion of sites to nonforest uses and an extensive road network, coupled with rapid, initial attack response times have dramatically changed fire patterns in this ecosystem. Lightning fires driven by shifting winds historically molded habitats that were much more structurally diverse than those managed today with rigidly scheduled line-fires set under predictable dormant-season weather conditions. The increasing use of variable growing-season fire regimes (currently about 15 to 25 percent of the total acreage), point-source ignitions (both aerial and ground), and “soft” firelines should help ameliorate this problem over time. Burn schedules that incorporate variability into season, frequency, and pattern of burn can be found in Robbins and Myers (1992). Streng and others (1993) and Olson and Platt (1995) suggested that many fires during the same season over time are necessary to produce changes in groundcover species composition.

Whenever the short fire-return interval is disrupted, pines that are more prolific seeders or have faster juvenile growth, outcompete the shade-intolerant longleaf pine. Burning the site while these competitors are still seedlings or saplings will selectively favor longleaf pine. However, once any of the multinodal Southern pines attain a basal diameter of about 2 inches (in 3 to 4 years), they become fairly immune to girdling by low-intensity fire (Wade 1993; Wade and Johansen 1987). Assuming no bud damage, longleaf, slash, and loblolly pines all usually survive complete crown scorch except during late summer and early fall when death often results, regardless of bud damage

(Storey and Merkel 1960; Weise and others 1990). Any fire that kills buds during the growing season (crown consumption is a good visual indicator) greatly diminishes a tree's chances of survival (Wade 1985).

Desired fire-return intervals and timing of fire depend upon the objective. Early on, fire was advocated to facilitate regeneration (Long 1889), reduce hazardous fuel accumulations (Mattoon 1915), eliminate invading hardwoods (Ashe 1910), control brownspot (Siggers 1934), and manage rangelands (Wahlenberg and others 1939). Quail plantations along the Florida-Georgia border have burned annually to favor this game bird for close to 100 years (Stoddard 1931). Showy plants such as orchids and pitcherplants (fig. 4-11) that frequent acidic depressions can be maintained by conducting annual late-spring burns (Komarek 1982). Long-term repeated prescribed fire studies include the 18 year effects of fire to control hardwoods in southern Alabama (Boyer 1993), understory plant community changes in a longleaf pine-wiregrass ecosystem in southern Georgia resulting from several decades of dormant-season burns at 1, 2, and 3 year intervals (Brockway and Lewis 1997), and understory plant response to 30 years of prescribed burning at various frequencies and seasons on the Santee Experimental Forest, South Carolina (Langdon 1981).

The effect of recurrent fire on Southern pine growth is important when considering fiber production (Chambers and others 1986). Studies have shown reduced growth after prescription fire (Boyer 1987; Boyer and Miller 1994; Zahner 1989) as well as increased growth after damaging fire (Johansen 1975). Grelen (1978) reported no height growth effects after introducing fire in 5 year old slash pine plantations and then burning at various frequencies through 9 years of age. Care must be exercised when interpreting the literature pertaining to the effects of fire on growth. Some fires were conducted at inappropriate times, and the methodology used to analyze results of some studies was flawed (Streng and others 1993; Wade and Johansen 1986). High fireline intensities that consume foliage (fig. 4-12) and high-severity fires that cause root damage (by burning at low duff moistures) most likely will cause mortality and reduce growth of survivors (Wade 1985). Ill-timed growing season burns and firing techniques will kill mature longleaf pine (Boyer 1990b). A guide recommended for firing is to consider a maximum air temperature of 99 °F, a minimum relative humidity of 34 percent, and flank firing technique. Reducing hazardous buildup of the forest floor by alternative methods such as commercial pine-straw raking (baled and sold on the retail landscape market as an ornamental mulch) will also reduce longleaf pine growth the following year (McLeod and others 1979), because scarce nutrients are removed instead of recycled. The literature pertaining to

Figure 4-12—Percent survival of 1 to 8 year old planted loblolly pine after the first postfire year relates to percentage of live foliage consumption (Wade 1985).

the effects of fire on Southern pine was summarized and critiqued by Wade and Johansen (1986).

Chronic burning regimes result in an open parklike forest with a groundcover dominated by grasses and forbs (fig. 4-13). Not only are such plant communities aesthetically pleasing, but they also provide excellent wildlife habitat and high quality forage for cattle and deer. Many such landholdings are profitably managed for the simultaneous production of cattle, wildlife, and timber resources (Wade and Lewis 1987; Wade and Moss 1999). Detailed restoration and management options for this species across its range are presented in Brockway and others (1998), Farrar (1990), Hermann (1993), and Landers and others (1990, 1995); by accessing the Longleaf Alliance through the home page for the Auburn University School of Forestry; or by contacting the Tall Timbers Research Station in Tallahassee, FL, or the Joseph Jones Ecological Research Center in Newton, GA.

Slash Pine

Vegetation Dynamics—Slash pine (*var. elliottii*) is the chief conifer associate of longleaf pine on wet Coastal Plain sites throughout its natural range, which extends from coastal South Carolina through southern Georgia, the flatwoods of Florida, and across the Gulf Coastal Plain into Mississippi and Louisiana

Figure 4-13—Longleaf pine stand maintained by biennial growing-season fires near Thomasville, Georgia. Lack of longleaf pine reproduction is an artifact of decades of annual dormant-season burns that ended in 1986. Photo by Ken Outcalt, 1993.

(Lohrey and Kossuth 1990). It is a prolific seeder, has rapid juvenile growth, and becomes increasingly tolerant of fire with age. Because of these traits and the ease of handling seedlings, slash pine has been extensively planted. A 1980 survey showed that almost half of the 13 million acres (5.2 million ha) of slash pine resource had been planted (Haeussler 1983). Slash pine is perhaps the only native North American tree whose commercial range has undergone a successful large-scale expansion, through planting northward into Tennessee and westward into Texas where it is now naturalized (Stone 1983). Sheffield and others (1983) estimated slash pine occupied over 40 percent of the commercial forestland in Florida in 1980. A variety of slash pine (*densa*), which goes through an abbreviated grass stage somewhat like longleaf pine and is almost as fire tolerant, is confined to southern Florida and the Keys where it replaces longleaf pine (see chapter 7). General descriptions of the slash pine ecosystem can be found in Lohrey and Kossuth (1990), Grelen (1980), Myers and Ewel (1990), Stone (1983), and Stout and Marion (1993).

The most hydric slash pine sites are depressions such as bays, bayheads, titi swamps, and cypress pond margins embedded within the flatwoods matrix. Common associates are pond pine, loblolly pine, sweet bay, loblolly-bay, swamp bay, pondcypress and swamp tupelo, and bottomland hardwoods such as red maple,

Carolina ash, American elm, sweetgum, and water oak. On such sites slash pine generally develops a pronounced buttress (comprised mostly of bark) that protects the tree from heat-girdling during drought fires. Species diversity is low. Characteristic understory species include cyrillas, sweetpepperbush, lyonias, and buckwheat tree. Little groundcover is present except for sphagnum, ferns, and various greenbriers.

Slash pine was historically confined to wet sites because its susceptibility to fire when young kept it from successfully competing with longleaf pine on upland sites. With removal of the longleaf pine and efforts to exclude fire, slash pine has successfully invaded many of these drier sites. The suspected historical successional scenario is that most fires favored slash pine. The occasional severe drought fire topkilled the woody vegetation (although a few slash pine survived), slash pine reestablished when a seed source was nearby, hardwood rootstocks resprouted (except in deep-burning peat fires), and the cycle repeated over the next several decades (Clewett 1980; Hodges 1980). Without fire the slash pine component eventually disappeared because a good seedbed was lacking and existing woody vegetation shaded out established slash pine seedlings.

Boggy flatwoods border creek swamps and acidic depressions. Fire enters these ecosystems during

extended dry periods, which occur every couple of decades. Longleaf pine is the primary overstory associate with an understory of fire-adapted shrubs such as wax myrtle, gallberry, buckwheat tree, dahoon, and yaupon, and a ground cover of pitcherplants. These sites grade into slash pine flatwoods as the hydroperiod (the length of time the water table is above the soil surface) decreases with a several-inch rise in elevation and concomitant increase in fire frequency; with another several-inch rise, sites grade into pure longleaf pine stands where the fire regime is chronic. The more mesic sites support a rank understory of flammable vegetation, which produces some of the highest fuel loadings encountered in the South (table 4-2). Fuel consumption during extended dry-period wildfires can exceed 15 tons/acre (37 t/ha) after a decade or so of fire exclusion in fully stocked natural stands. Even high-intensity prescription fires do not approach this figure because burn plans almost invariably call for Keetch Byram Drought Index (Keetch and Byram 1968) values below 500 to avoid killing the overstory pine feeder roots that colonize the developing humus layer.

Extensive planting on old-field sites and decreased fire frequency have led to development of many other understory associations including saw palmetto, dwarf huckleberry, ground blueberry, and grasses such as Curtis' dropseed, broomsedge, and chalky bluestem and the creeping variety of little bluestem. Planting on xeric, nutrient-poor deep sands (ancient sand dunes) has resulted in associations with sand pine and numerous oaks such as post, blackjack, sand live, myrtle, bluejack, and turkey (Lohrey and Kossuth 1990). Planting of slash pine outside its natural range has resulted in many additional plant associations, virtually all of which are also fire-adapted.

Management Considerations—Harvesting of longleaf pine and fire exclusion policies in the first half of the 20th century, followed by several decades of extensive planting of slash pine coupled with dormant-season backing fires at wider than needed time intervals, resulted in a significant invasion of slash pine and its accompanying rank understory into former mesic longleaf pine sites. Most landowners were reluctant to use head fires, or in many cases any fire, because of high fuel loadings. Low-intensity backing fires rarely penetrated into the more mesic flatwoods because of high water conditions during the winter from frequent rainfall and reduced evapotranspiration.

During the 1980s, fire management of this pine resource changed dramatically due to the advent of aerial ignition, use of growing-season prescribed fires, recognition that the aesthetically pleasing longleaf pine ecosystems had virtually disappeared, and an increased appreciation of ecosystem management. The objectives included an increase in fire frequency to

reduce the potential for catastrophic fire and the desire to directly or indirectly promote longleaf pine and its associated biologically diverse groundcover. On many lands, plowed firelines are no longer the norm, the fire-free interval has been shortened and high-intensity headfires are purposely run into the encroaching walls of underbrush to push the ecotone back toward historic boundaries (Ferguson 1998). These ecotones are not static, and as water tables are permanently lowered, they move further downslope.

The relationship between fire and major pests of slash pine has received limited study. However, studies suggest that use of prescribed fire can reduce the severity of annosus root rot (Froelich and others 1978) and fusiform rust (Siggers 1949; Wade and Wilhite 1981), two serious diseases of slash pine. Southern pine beetle infestations are not influenced by the judicious use of fire, but fires that result in severe crown scorch or root damage are often a precursor to attack.

Fire management in slash pine stands is straightforward. Fire has to be withheld for 3 to 5 years until sapling girth at ground level exceeds 2 inches (Johansen and Wade 1987a). After 8 or 9 years, slash pine usually recovers from complete crown scorch during all seasons except early fall (Weise and others 1990); however, its growth will be severely impacted (Johansen and Wade 1987b). Slash pine will not recover if buds are killed by complete consumption of foliage. Eye-level winds within stands are necessary to give the flame front direction and dissipate heat, but the controlling variable for effective use of fire is forest floor moisture content; if it is too high, fires will not back, whereas if too low, significant damage occurs to feeder roots. The water table level as measured by the Keetch-Byram Drought Index (KBDI) should be considered in planning prescribed fires because during severe droughts (KBDI above about 600), fires will burn through boggy flats and bayheads consuming underlying organic soils and destroying hardwood rootstocks as well as those of overstory trees. General guides for using fire in slash pine can be found in de Ronde and others (1990) and Wade (1983).

Loblolly Pine

Vegetation Dynamics—Loblolly pine dominates about 30 million acres (12 million ha) from New Jersey south to Florida and then west to Texas with excursions into Oklahoma, Arkansas, and Tennessee interrupted only by the flood plain of the Mississippi River (Baker and Langdon 1990). Loblolly pine historically was confined to much of the same wet landscape as slash pine for the same reason—its susceptibility to fire when young. It is also common along stream bottoms in the Piedmont where fire-free intervals historically exceeded 5 to 6 years. With increased fire

protection, acreage dominated by this species dramatically increased as it seeded into former longleaf pine sites and abandoned agricultural lands. Loblolly pine was planted even more extensively than slash pine. It is currently the leading commercial tree in the Southern United States, comprising more than half of the standing pine volume in the region (Baker and Langdon 1990).

Loblolly pine is currently found on many of the same sites as slash pine except deep sands, but because of its greater range it occurs in association with many more species, especially where fire frequency has been reduced. Wahlenberg (1960) lists over 60 principal associates. Descriptions of various ecosystems where loblolly is a major component can also be found in Baker and Langdon (1990), Crow (1980), and Skeen and others (1993). On drier sites, longleaf, shortleaf, and Virginia pines; southern red, white, post, and blackjack oaks; mockernut hickory; and common persimmon are all common overstory associates. At the other end of the elevation-moisture gradient, associates include slash pine and pond pine; water, willow, southern red, swamp chestnut, and laurel oaks; southern magnolia; swamp tupelo; American elm; and red maple.

Because loblolly pine favors sites where soil moisture is not limiting, plant community composition usually includes a dense species-rich understory. Common understory hardwoods and vines usually resprout after fire. Herbaceous groundcover is typically sparse and includes bluestems, panicums, and longleaf uniola. Oosting (1944) compared differences in vegetation between an unburned area and two levels of fire intensity 9 years after a wildfire in a 35 year old stand of old-field loblolly pine. Species composition was about the same on all three areas. Although the crown fire killed virtually all overstory pines, many pine seedlings established and were successfully competing with hardwood sprouts suggesting that the future stand would again be mixed pine-hardwood. Twenty years of prescribed burning on the Georgia Piedmont at a 4 to 5 year cycle showed that the understory was drastically reduced and wildlife habitat improved (Wade and others 1989). Species composition in comparison to adjacent unburned stands was not altered. The same trends were noted on the Coastal Plain of South Carolina except where annual growing-season fires extirpated some hardwood species (Langdon 1981; Waldrop and others 1987).

Management Considerations—The key to managing loblolly pine is control of understory hardwoods, which is usually accomplished with periodic fire (fig. 4-14), mechanical methods, and chemicals (Chaiken and LeGrande 1949; Chapman 1947; Grano 1970; Harshbarger and Lewis 1976; Trousdell 1970). Where precipitation is a limiting factor, especially

Figure 4-14—Growing-season prescribed fires topkilled more hardwoods and larger ones than dormant-season fires. Data collected on Brender Demonstration Forest, Georgia.

toward the western edge of its range, hardwood control can increase the growth of overstory pine (Bower and Ferguson 1968; Grano 1970). Loblolly pine is easily killed by fire when young, although seedlings will sometimes resprout at the root collar. On all but the poorest sites, juvenile height growth is several feet per year and its bark rapidly thickens, becoming resistant to light surface fires by the time stem diameter at ground level reaches 2 inches (5 cm) (Wade 1993).

Operational underburning in loblolly pine is usually not advocated until stands reach about 10 years of age, but the sooner prescribed fire is used, the easier it is to topkill competing hardwoods. If care is taken in selecting burning conditions and in executing the burn to avoid crown scorch, plantations can be safely burned at half this age. Fire has been advocated as an integral part of the conversion from low-grade hardwood stands that developed with fire exclusion, back to loblolly pine or shortleaf pine. Planted loblolly exhibited increased growth on sites where hardwoods were cleared and burned (Applequist 1960). Numerous authors including Brender and Cooper (1968) and Cooper (1973b) described the use of fire to prepare mineral soil seedbeds to facilitate natural regeneration of loblolly pine.

Low-intensity, low-severity fires can be used to prepare seedbeds on steep slopes without triggering erosion problems (Douglass and Van Lear 1982; Van Lear and others 1985). The benefits to wildlife from repeated prescribed fires in loblolly pine stands are described well by Cushwa and Redd (1966) and Cushwa and others (1966). Guides to the management of this species include Brender (1973), Schultz (1997), and Wahlenberg (1960).

Shortleaf Pine

Vegetation Dynamics—The range of this species extends from southern New York southwest across southern Pennsylvania, Ohio, Indiana, Illinois, and Missouri, then south through eastern Oklahoma and Texas, and all States to the east including northern Florida (Mattoon 1915). It has the widest range of any of the eastern pines, occurring in 22 States. It occupies a wide variety of soils and environmental conditions but does not tolerate poorly drained sites. Shortleaf pine does well only on mineral soil seedbeds. It is a prolific seeder, often forming dense sapling stands that are favored over competing hardwoods by frequent fire.

Shortleaf pine can sprout repeatedly from its base if the tree is topkilled (see chapter 2). Trees 30 years old can produce basal sprouts (Little and Somes 1956); however, Mattoon (1915) and Wakeley (1954) reported that this species loses its ability to sprout when less than half that age. Many sprouts can arise (70 or more), but virtually all die once a central leader assumes dominance (Komarek 1982). In a 1912 survey of shortleaf pine in Arkansas, few stands were found that originated from seedlings because of pervasive fire. There were more than three age classes of coppice in many stands (Mattoon 1915). Ability to resprout, abundant seed crops, rapid juvenile growth (especially of sprouts), and a low resin content of the wood make this species markedly tolerant of fire (Mattoon 1915). Trees larger than 0.5 inch (1.3 cm) dbh are somewhat resistant to fire; mortality is negligible once trees reach 4 inches (10 cm) dbh (Walker and Wiant 1966). Like other Southern pines, trees over 5 feet (1.5 m) tall rarely die when crown scorch is less than 70 percent and buds are not killed by consumption of foliage.

Loblolly pine is the chief associate of shortleaf pine at lower elevations throughout the Mid-South and Southeast. Loblolly pine dominates the heavier, moist soils while shortleaf pine dominates the lighter, drier soils. Loblolly drops out at about 400 feet (122 m) elevation in the Ozarks and Ouachitas, resulting in pure stands of shortleaf pine up to about 2,000 feet (610 m) on south-facing slopes, above which hardwoods begin to dominate with shortleaf pine disappearing at about 3,000 feet (914 m). In the Appalachians and Upper Piedmont, Virginia pine replaces

shortleaf pine on drier nutrient-poor sites east of the Appalachian divide. On the New Jersey Coastal Plain, pitch pine is the chief associate of shortleaf pine. Common hardwood associates are oaks (red, black, post, and chestnut), hickories (pignut and mockernut), sweetgum, yellow poplar, red maple, common persimmon, flowering dogwood, and sassafras.

Management Considerations—Mineral soil seedbeds are preferred but not required for seed germination (Boggs and Wittwer 1993; Ferguson 1958; Loyd and others 1978). Burns that expose mineral soil seedbeds may compact the surface soil as observed in the Arkansas mountains (Bower and Smith 1962). Care should be taken when using fire in hilly terrain because of the potential for erosion, especially on drier sites in the western part of its range (Moehring and others 1966). When low-severity fires are used to avoid consuming the humus layer, soil movement is negligible, even on steep Appalachian sites (Van Lear and Danielovich 1988). Shortleaf pine competes poorly with other plants (Williston and Balmer 1980). Periodic low-intensity fires, herbicides, or both are necessary to control the relentless encroachment of hardwoods and improve growth of the pines (Bower and Ferguson 1968; Crow and Shilling 1980; Ferguson 1957; Grano 1970; Hodgkins and Whipple 1963; Little and Moore 1950; Rogers and Brinkman 1965; Yocom 1972). Understory hardwoods deplete soil water in pine stands (Zahner 1958).

Somes and Moorhead (1950) showed that prescribed fire does not reduce the yield from oak-pine stands in New Jersey. Additional evidence showed that timber harvest and prescribed fire are not nutrient depleting practices and can enhance soil nutrient levels (Masters and others 1993). Phillips and Abercrombie (1987) demonstrated that excellent stands of shortleaf pine and mixed hardwoods could be produced by the fell and burn technique. Guides for managing shortleaf pine include Chen and others (1975, 1977), Nickels and others (1981), and Walker and Wiant (1966).

Oak-Hickory Forests

Pre-1900 Succession—Frequent fires ignited by Native Americans maintained open oak-hickory forests with a groundcover of grasses and forbs (fig. 4-15). Oaks and hickories were favored because of their thick bark. These species dominated the canopy as old, large, fire-resistant trees. Densities of dominant trees probably varied from 20 to 40 per acre. Shrubs, understory trees, and woody debris were rare (Barden 1997; Buckner 1983; Denevan 1992; Pyne 1997). Hardwood regeneration comprised seedling sprouts dominated by oak and hickory because these species initially emphasize root development over stem growth and have the ability to sprout repeatedly (Barnes and Van

Figure 4-15—Oak-dominated stand after 10 annual spring burns on the Cumberland Plateau, eastern Tennessee. Photo by Ivan Thor, 1976.

Lear 1998; Brown 1960; Van Lear 1991). With fire excluded for a few years, the well-developed rootstocks sent up vigorous stems that often developed sufficient size and bark thickness to withstand future fires. Where windstorms blew down trees over large areas, the replacement stand was even aged. Consequently, the forest was uneven aged, consisting of even aged patches.

Post-1900 Succession—The exclusion of fire from fire-dependent oak ecosystems should be considered a catastrophic disturbance according to Packard (1993). Reduction of fire has profoundly changed the oak-hickory forest by allowing the forest to succeed to mixed mesophytic and northern hardwood species such as red maple, eastern white pine, sugar maple, and beech (fig. 4-7). In the absence of fire, these species become established in the understory, grow into the midstory, and eventually change the composition of the canopy. Stem densities are often hundreds per acre. During the growing season, the dense shade from these fire-sensitive species reduces the abundance and richness of forbs and grasses and inhibits development of oak and hickory regeneration. Consequently, when a dominant oak or hickory dies, its reproduction is not capable of sufficient growth to capture the canopy opening. Instead, the growing space is filled by mesophytic and northern hardwood species (Abrams and Downs 1990; Crow 1988; Lorimer 1985; McGee

1984). According to Olson (1996), the brushy character of many sites is the result of an interruption in the chronic fire regime that allows shrubs and hardwoods to capture the site. When the area again burns several years later, these stems are top killed producing a dense growth of sprouts that can dominate the site for decades, especially with occasional fire.

On drier mountainous sites, fire exclusion allows ericaceous shrubs such as mountain laurel and rhododendron to move from riparian areas into upland forests (Elliott and others 1999). These shrubs are shade tolerant and evergreen, shading the forest floor throughout the year. Hardwoods cannot regenerate beneath them (Baker and Van Lear 1998), and without disturbance, these heath thickets are the climax plant community on some sites. Although the forest floor rarely dries enough to support surface fire, the ericaceous shrub layer is flammable; and when it burns, it typically supports intense, stand-replacement fires that alter successional pathways, reduce site productivity, negatively impact involved streams, and threaten human life and property (such slopes are favored building sites). Altered fire cycles have also impacted the “low elevation rocky summit” vegetation type where fire historically maintained the hardwood scrub savanna (Hallisey and Wood 1976). Fire exclusion over the past 50 years resulted in an increased hardwood overstory and a dramatic decline in herbs

such as blazing star and some woody scrub species such as bear oak (Barden 2000).

Management Considerations—Until recently, foresters failed to appreciate the role of fire in maintaining open oak-hickory forests and in facilitating regeneration of these species (Lorimer 1993). Regeneration of oak was attempted only with timber harvesting and herbicides, which generally hastened the successional replacement of oaks by mixed mesophytic species (Abrams and Scott 1989). Research indicates that fire can be used in hardwood stands to establish and release oak-hickory regeneration (Barnes and Van Lear 1998; Brose and Van Lear 1998, 1999; Christianson 1969).

Understory burning of mature, uncut hardwood stands can help establish oak and hickory regeneration by preparing a seedbed (Barnes and Van Lear 1998). Acorns and hickory nuts are often buried by wildlife, particularly squirrels and blue jays, which prefer burned areas because of the thin root mat. The fires also top-kill or eliminate many of the shrubs and small trees that shade the forest floor. In a less shaded environment, the acorns and hickory nuts germinate and the new seedlings begin developing their root systems. Eventually, the regeneration replaces canopy trees. In this approach, fires are initially applied at a frequent interval (annual or biennial) depending on season of burn and severity of the shade. Once oak seedlings are established, fire is withheld for a few years (Cottam 1949), and then periodically reapplied once or twice a decade. This minimizes mortality of the oak regeneration by allowing time for root systems to develop. This approach may take 15 to 20 years for results to be apparent.

If oak and hickory regeneration is present in the understory, a two-step shelterwood harvest combined with a prescribed fire can be used for release (Brose and others 1999a,b). The initial shelterwood cut reduces the basal area to about 50 sq. feet/acre (11.5 sq. m/ha) removing low-value stems. The regeneration is allowed to develop for 3 to 5 years. During this time, oak and hickory regeneration develop large root systems but exhibit little height growth while their competitors do the opposite. When the root collar diameter of the oak regeneration is about 0.75 inch (2 cm), a growing-season prescribed fire with flame lengths of 3 to 4 feet (about 1 m) is used to kill the regeneration layer. This treatment will completely kill the less fire-tolerant competing hardwoods (Christianson 1969), invading eastern white pine (Blankenship and Arthur 1999), and rhododendron and mountain laurel. Few oaks and hickories will be killed by the fire, and most will sprout and grow vigorously. Regeneration should be inventoried 2 to 3 years later to determine whether additional fires are needed.

When using the shelterwood-burn technique, care must be taken to protect dominant oaks from basal fire damage. Directional felling during the logging operation is recommended so that the resultant slash is not abutting the trees. Otherwise, slash must be removed from the bases of dominant oaks to prevent fire damage. Generally, damage to dominant oaks is not a problem when burning in uncut stands because fuel loadings are considerably lighter. Graphs or equations can be used to predict mortality of several oak species after fires of varying intensity (Loomis 1973). The shelterwood-burn technique appears to be a reasonable mimic to the disturbance regime of oak-hickory forests before Euro-American influence. It has considerable value as a silvicultural method, a wildlife management tool, and a means for restoring habitats such as oak savannas and open woodlands.

Mixed Fire Regimes

Major Vegetation Types

The mixed fire regime best represents the presettlement fire history for several hardwood and conifer dominated ecosystems. The conifers include pitch pine and Virginia pine of Kuchler's oak-pine association and pond pine, a dominant tree of the pocosin association (table 4-1). The conifer types fit the mixed fire regime because fire intensities are generally greater than in the understory fire regime and cause mortality ranging from 20 to 80 percent of the overstory. The hardwood ecosystems comprise mesophytic hardwoods, Northern hardwoods, and elm-ash-cottonwood ecosystems (table 4-1). Although the hardwoods are prone to fire injury, many survive numerous fires before eventually being girdled. These fires tend to be low-intensity due to less flammable fuels than found in ecosystems having a substantial conifer component. We believe that the low-intensity presettlement fires that wounded and killed many trees did not cause enough mortality (>80 percent according to our criteria) to be considered stand-replacement.

Pines

Pitch Pine—Pitch pine grows on poor, generally sandy, gravelly, and shallow soils, primarily south of the glaciated region in southern New England in a fairly wide swath following the Appalachians and Upper Piedmont into Georgia where it occurs below 3,000 feet (914 m) elevation (Little 1959; Little and Garrett 1990). In New Jersey, pitch pine commonly exists in two forms, as a tree interspersed with hardwood trees (Pine Barrens) or as a member of a scrub oak community (Pine Plains).

Virginia Pine—The natural range of this species stretches from New Jersey across southern Pennsylvania to Indiana, then southward into central Alabama, and then northeasterly up the eastern slope of the Appalachians with more than half the standing inventory in western Maryland, Virginia, and North Carolina (Sternitzke and Nelson 1970). Virginia pine characteristically occupies poor sites where it often forms pure stands. Common associates include shortleaf, loblolly, and pitch pines; eastern redcedar; numerous oaks (SAF cover type Virginia pine-southern red oak); and other hardwoods.

Pond Pine—This forest cover type (SAF 98) stretches along the Coastal Plain from New Jersey to Alabama dominating poorly drained sites characterized by organic soils such as pocosins, bays, and shrub bogs where it often forms pure stands (Wenger 1958). About 80 percent of the pond pine forest is in the Carolinas (Sternitzke and Nelson 1970). Pond pine communities are often referred to by the understory vegetation such as shrub bogs or pocosins. The Native American name pocosin means swamp on a hill and they are just that. They occur on divides between rivers and sounds but are not alluvial. They all have long hydroperiods, burn periodically and are underlain by sandy humus or organic peat or muck soils (Richardson and Gibbons 1993). Pocosins, shrub bogs, and Carolina bays are often found within the loblolly pine, slash pine, slash pine-hardwood, and sweetbay-swamp tupelo-redbay cover types. On well-drained sites, pond pine is usually a minor component.

Hardwoods

Mixed Mesophytic Hardwoods—These forests occupy the transition zone from the oak-hickory forest to the northern hardwood forest. They are among the most diverse in the United States containing more than 30 canopy tree species. This type lies west of the Appalachians and transitions from the more northern sugar maple-beech-birch forest in northern West Virginia, southwestern Pennsylvania, and southern Ohio southward down the Allegheny Mountains, across the Allegheny Plateau including all of the Cumberland Plateau, and into northern Alabama where it transitions to the oak-hickory-pine type of the Southern Mixed Hardwood Forest. Common overstory species include sugar maple, red maple, basswood, northern red oak, chestnut oak, white oak, yellow poplar, American ash, silverbell, yellow birch, southern magnolia, Blackgum, black walnut, beech, yellow buckeye, and butternut.

Northern Hardwoods—The maple-beech-birch FRES ecosystem type, commonly known as Northern hardwoods, occurs on mesic and fire protected sites in the Lake States, Northeast, and Southeastern Canada

(fig. 4-16). The dominant hardwood species include sugar maple, yellow birch, beech, and basswood in the Midwest. Northern hardwoods mix with boreal spruce and fir to the Northeast and with eastern hemlock, eastern white pine and northern oaks to the south and west. Component species, especially beech and sugar maple, extend south at mid elevations in the Appalachian Mountains to western Virginia and North Carolina where they occur in Kuchler's mixed mesophytic forest type.

Bottomland Hardwoods—This is the FRES elm-ash-cottonwood ecosystem type that occurs in narrow belts along major streams or scattered areas of dry swamps. The major portion is on the lower terraces and flood plains of the Mississippi, Missouri, Platte, Kansas and Ohio Rivers (Garrison and others 1977). This type comprises Kuchler's Southern and Northern flood-plain forest types and the elm-ash forest. Nineteen SAF forest cover types are included in these bottomland hardwood forests (Shartz and Mitsch 1993). Length of hydroperiod, which determines the anaerobic gradient (Wharton and others 1982), rather than fire frequency, determines plant distribution. Common canopy species include numerous oaks, sugarberry, American elm, eastern cottonwood, green ash, sweetgum, sycamore, and in deeper water, swamp and water tupelos, and bald cypress.

Fire Regime Characteristics

Pitch and Virginia Pines—Mixed severity fires were probably prevalent over much of the range of pitch and Virginia pines. Where Native American burning was common, pitch pine existed as an understory fire regime type. Understory fires were common in pitch pine forests where burning by Native Americans resulted in a 2 to 10 year fire interval. This

Figure 4-16—The extent of northern hardwood forests in northeastern North America. Redrafted from Bormann and Likens (1979).

frequency maintained stands with relatively large pines, scattered smaller pines and oaks, and little understory besides low ericaceous shrubs and herbs (Little 1946, 1973). Today, the mixed fire regime type applies, at least in the New Jersey Pine Barrens, because fire return intervals are longer and the majority of wildfires occur during the growing season when damage is greater. The historical fire regime in Virginia pine is unknown but was probably less frequent and resulted in higher mortality.

Pond Pine—Most pocosins burn on a 20 to 50 year cycle (Christensen and others 1988). On better sites, fire-return intervals range from about 3 to 10 years and at the short end, can result in pine savanna with a grass understory. On organic soil sites, such short return intervals result in herb bogs. Historically, more frequent fire in the adjacent longleaf-dominated uplands killed encroaching seedlings thereby confining this species to wetter areas. These wet sites, however, burned whenever they were dry enough. The rank shrub layer characteristic of these mesic areas comprises many ericaceous evergreen shrubs that tend to burn intensely, resulting in the topkill or death of all vegetation except pond pine. Pond pine has the ability to resprout from its base (fig. 4-17) and along its stem and branches (Wenger 1958); thus, its aboveground stem survives higher intensity fires than stems of other pine species. This trait allows the species to

dominate wet areas such as pocosins, which support intense fires. Summer fires during severe drought usually eliminate the pond pine as well, because the underlying organic soil burns, destroying the root systems.

Mixed Mesophytic Hardwoods—Although little is known about presettlement fire, it appears that fire was much more common in the mesophytic forests west of the Appalachian divide than in those to the east. Harmon (1984) reported the fire return interval on south-facing slopes in extreme western Great Smoky Mountain National Park averaged 10 to 12 years between 1850 and 1940 when fire exclusion was begun in earnest. In a summary of fire in the Appalachians, Van Lear and Waldrop (1989) stated, “Forests of the Southern Appalachians probably did not burn as frequently as the pine-grasslands of the adjacent Piedmont. However, there can be no doubt that they did burn periodically.” Buckner (1989) described fire’s evolutionary importance in determining the vegetative mosaic of this region. Harmon and others (1983) thought that fires in the mixed mesophytic region were small and restricted to drier sites.

Northern Hardwoods—Although data are limited, evidence suggests that fires rarely occurred in presettlement Northern hardwood forests (Foster and Zebryk 1993; Patterson and Backman 1988). Fire return intervals of many centuries are consistent with

Figure 4-17—Pond pine basal sprouts 1 year after wildfire topkilled the overstory. Photo by Dale Wade, 1972.

land survey records (Siccama 1971; Lorimer 1977) and paleoecological data (Patterson and others 1983) in the Northeast. Lorimer (1977) calculated a fire rotation of 806 years, but argued that this figure was too low due to the effect of land clearing on his data. Based on a study of maple-beech forests in Ohio, Runkle (1990) concluded that the minimum fire-return interval was greater than a canopy generation. In the Bigwoods maple-basswood forest of Minnesota and Southeastern Ontario, fire probably occurred more frequently due to Native American burning practices that allowed prairie fires to spread eastward into the Bigwoods (Grimm 1984; Vankat 1979).

Where conifers such as hemlock and spruce were substantial components of the hardwood forests, stand-replacement fires probably occurred more often (Nichols 1913), in which case the stand-replacement fire regime may be a better representation of presettlement fire. Portions of the Northern hardwood forest were visited so infrequently by fire prior to settlement that a strong case could also be made to place this forest type in the nonfire regime (table 4-1).

Bottomland Hardwoods—The historical role of fire in the bottomland hardwood ecosystem is unclear. In Mississippi, Lentz (1931) stated that low- to moderate-intensity wildfires were frequent and that 80 to 90 percent of the Mississippi delta hardwood forest showed evidence of damage. Gustafson (1946) and Toole (1959) presented evidence of disastrous consequences to the hardwoods from repeated fires. In Louisiana, Kaufert (1933) dated fire scars on stumps back prior to the Civil War, but based on the recollections of “old-timers,” he did not think widespread burning of these bottoms occurred until about 1890. Low-intensity fires are the norm in these forests because fuel loadings are generally light (except after damaging wind storms) due to rapid decomposition on these moist, humid sites. In the canebrakes, fire intensity was much higher although fire severity was low except during drought. Large fires occur only after extended drought, usually a dry fall followed by a dry spring.

Fuels and Fire Behavior

Pines—The typical lowland wildfire in **pitch pine** on the Pine Plains of New Jersey advances as a wall of flame consuming overstory pine crowns and leaving a stubble of shrub skeletons unless the underlying organic soil is also consumed, which occurs during severe drought fires (Little 1979). Fires in the Pine Barrens tend to be of lower intensity and more like fires elsewhere in pitch pine stands. Even on steep slopes of the Southern Appalachians where pitch and Table Mountain pine grow together, more than 20 percent of the overstory trees typically survive, although more intense stand-replacement fires

occasionally occur. The short needles of **Virginia pine** form a relatively compact forest floor, which dries slowly and is conducive only to light surface fires (Little 1974).

Fuels in pocosins occupied by **pond pine** comprise varying proportions of shrubs, switchcane, and grasses. High intensity fires can occur where high fuel loadings accumulate, often including a rank growth of ericaceous shrubs. Typical live fuel and litter loadings are 6 to 8 tons/acre (13 to 18 t/ha) in low pocosins (about 4 feet high) (fig. 4-18), 8 to 10 tons/acre (18 to 22 t/ha) in medium height pocosins (about 5 feet high), and upwards of 15 tons/acre (34 t/ha) in high pocosins (about 14 feet high) (Wendel and others 1962). Some pocosin sites are depicted in a stereo photo series (Ottmar and Vihnanek, in press). The probability of blowup fires occurring in pocosins ranges from low in low pocosins to high in high pocosins.

Northern Hardwoods—Hart and others (1962) estimated average annual litterfall in a New Hampshire Northern hardwood stand at 1.4 tons/acre (3.16 t/ha). Leaf litter decomposition rates reported as half-times (years required to lose one-half of the original dry weight) ranged from 1.1 years for yellow birch to 2.5 years for beech, which are high (Gosz and others 1973). Accumulated duff is typically 2 to 3 inches (5-8 cm) in depth (Hart and others 1962).

Gore and Patterson (1986) sampled downed wood in Northern hardwood stands including a large tract of old-growth Northern hardwoods, and a recently clear-cut stand in New Hampshire. Loadings of material <1 inch (2.5 cm) in diameter were low, ranging from 0.4 to 2.7 tons/acre (1 to 6 t/ha) across all but the recently cut stand (table 4-4). The total mass of downed wood declined precipitously in the first 10 years following cutting and stabilized at 18.7 tons/acre (42 t/ha) in the old-growth stand (fig. 4-19). Patterson and others (1983) reported similarly low total woody fuel loadings for Northern hardwood stands burned in 1947 and about 1880 in Acadia National Park, Maine. Total dead fuel loadings averaged 10.0 tons/acre (22.4 t/ha) and 11.8 tons/acre (26.5 t/ha), respectively, with duff depths of 2.3 and 1.0 inches (5.8 and 2.5 cm).

Postfire Plant Communities

Pitch Pine

Vegetation Dynamics—Pitch pine is well adapted to fire having thick bark, serotinous cones, and the ability to refoliate from dormant buds located along the stem and branches, or from the basal crook located just below ground line (Little 1979). A majority of the trees have serotinous cones especially where fires are severe (Little 1974). Seed is produced at an early age, 3 to 4 years for sprouts and 10 years for seedlings

Figure 4-18—Low pocosins maintained by periodic wildfire, eastern North Carolina. Photo by Walter Hough, 1973.

(Little 1953). Pitch pine is much more resistant to fire than its hardwood competitors. Fire every 4 to 6 decades will ensure a pitch pine component. As fire frequency increases, the importance of pitch pine in the stand also increases. Repeated intense fires at less than 20 year intervals will eliminate even its fire-adapted associates such as shortleaf pine, which take longer to produce viable seed (Little 1974). Shortleaf pine also produces basal sprouts when topkilled, but loses this ability with age while pitch pine can do so indefinitely (Little and Somes 1956). In the Pine Barrens, most associates are sprouters so that total cover surpasses 100 percent the first year after wildfire, severely restricting light and space for obligate seeders (Boerner 1981). The relationship between fire

frequency, intensity, and severity, and their effect on postfire succession is discussed by Little (1979).

Common associates on upland sites in New Jersey include shortleaf, Virginia, Table Mountain and eastern white pines; black, white, northern red, southern red, chestnut, bear, post, scarlet, and blackjack oaks; and various hickories (Little 1973,1979; Little and Garrett 1990; Murphy and Nowacki 1997; Wright and Bailey 1982). Elsewhere eastern white pine is a common associate and outcompetes pitch pine in the absence of continued fire.

Successional trends following fire are toward domination by hardwood species. Without disturbance, pitch pine declines (Smith 1991; Vose and others 1994). On upland sites, trees usually invade much

Table 4-4—Average loading (tons/acre) of downed wood by diameter class (inch) and time since cutting for New Hampshire northern hardwood stands (Gore and Patterson 1986).

Diameter	Years since stand was clearcut				
	1	15	50	100	Uncut
0 to 0.25	3.4	1.1	1.5	0.5	0.9
0.25 to 1	6.5	2.2	2.4	2.7	2.4
1 to 3	17.8	1.7	2.9	1.0	2.1
>3	10.8	9.5	7.6	20.1	13.3
Total	38.5	14.5	14.3	24.3	18.7

Figure 4-19—Downed wood in old growth Northern hardwoods on the Bowl Research Natural Area, White Mountain National Forest.

faster than understory shrubs such as huckleberries and blueberries (Little 1979; Little and Moore 1949). On mesic to wet sites, fire exclusion leads to replacement by red maple, blackgum, sweetbay, American holly, and gray birch (Little 1979). Shrub encroachment is also much faster, and dense understories of sheep laurel, piedmont staggerbush, gallberry, and leatherleaf often quickly develop.

Management Considerations—On xeric mixed pine-hardwood ridges in the Southern Appalachians, fire has been advocated to restore diversity and productivity (Swift and others 1993; Vose and others 1994, 1997). Where pitch pine occurs with oaks and shortleaf pine in New Jersey, it is favored by winter fires that produce good seedbeds. In the Pine Barrens, a fire return interval of 12 to 16 years is used to maintain pine-oak stands. However, low-intensity winter prescribed burns have little effect on hardwoods (Little 1973). Boerner and others (1988) found that hardwood growth was actually increased by winter prescribed burns, suggesting that these fires were counterproductive. Competing hardwoods can be best controlled by applying a winter fire that reduces surface fuels followed by a summer fire. Deep-burning fires are needed on deep organic soils to prepare seedbeds and kill competing hardwoods; however,

smoke management constraints generally severely curtail opportunities for such burns. Several underburns 8 to 16 years apart will reduce huckleberries while favoring an herbaceous ground cover including mosses and lichens (Buell and Cantlon 1953) that benefit many wildlife species from butterflies to quail. But according to Boerner (1981), species richness peaks the first year postfire and declines precipitously as resprouting heath cover closes toward the end of that first growing season.

In the middle of the Pine Barrens, intense, frequent fires (every 8 years or so) over a long period have eliminated virtually all large trees. The result is a low shrubby plant community consisting of a 3 to 7 foot (1 to 2 m) tall coppice growth of pitch pine, blackjack oak, bear oak, and mountain-laurel (Little 1946; Little and Somes 1964; Lutz 1934; Windisch and Good 1991). Repeated surface fires with moderate fire intensities can transform Pine Plains on xeric uplands into taller, less dense stands due to selective survival and growth of taller stems. Frequent crown fires (<20 year intervals) will maintain the Plains type. To preserve this unique ecosystem, fire frequency and severity should be varied to produce a diversity of stand ages, structures, and patch types (Windisch and Good 1991). Without fire, scrub type pitch pine eventually forms an overstory (Little 1998).

Roughly 4,000 acres of relic pitch pine barren ecosystem known as the Albany Pine Bush occurs in upstate New York. With periodic fire, pitch pine and scrub oaks (bear and dwarf chinkapin) predominate; but in the absence of fire, broadleaved hardwoods including red and white oaks, red maple, and white ash become established (Milne 1985). Prescribed fire is currently used on a 10 year return interval to restore and maintain this ecosystem, which provides habitat for the Federally endangered Karner blue butterfly. See Walker (1967) for discussion of management recommendations pertaining to pitch, Virginia, and pond pines.

Virginia Pine

Vegetation Dynamics—Virginia pine tends to dominate only on nutrient-poor, xeric sites (Mattoon 1915; Williston and Balmer 1980) where other species have trouble surviving. Virginia pine has only localized commercial importance. Although classed as a southern yellow pine and often exhibiting more than one flush during the growing season, it is much less tolerant of fire than the major Southern pine species because of its thin bark. Young trees sometimes produce basal sprouts when topkilled.

Management Considerations—Although pole-sized stands have been treated with low-intensity, winter season prescribed fire without overstory mortality in New Jersey, fire use should be considered experimental because of the likelihood of mortality. Most wildfires kill a majority of the stand because the thin, compact forest floor will only burn under relatively hazardous conditions. These fires, however, are usually responsible for regenerating the species. Fire is an effective tool for eliminating Virginia pine in mixed pine stands (Slocum and Miller 1953). Prescribed fire was recommended for preparing a seedbed for the next crop after harvest (Church 1955), and to increase seedling vigor (Sucoff 1961).

Pond Pine

Vegetation Dynamics—Pond pine has semi-serotinous cones, which are often produced by age 4 to 6 and open slowly over a period of years in the absence of fire (Wenger 1958). Seeds released from cones opened by fire almost invariably result in a blanket of reproduction, some of which survive the next fire if given 5 to 10 years to develop. Seedlings tend not to resprout, although they can in some situations.

Common associates are loblolly and slash pines, cabbage palmetto, Atlantic white-cedar, pond cypress, bald cypress, swamp tupelo, sweetbay, loblolly-bay, redbay, sweetgum, and red maple. Greenbrier is almost always a component of the understory along with switchcane, gallberry, large gallberry, swamp cyrilla,

wax myrtle, saw palmetto, and sweetpepperbush (Bramlett 1990; Wenger 1958).

Different successional pathways producing various community types result from the interaction between fire frequency, fire intensity, hydrology, and organic soil depth (McKevlin 1996; Wharton 1977). The original pocosins once covered more than 2.5 million acres (1 million ha) in North Carolina alone (Richardson 1981), but only a fraction of that remains because of peat mining, drainage, and conversion to pine plantations or row crops. For overviews of this ecosystem see Richardson and Gibbons (1993) and Stout and Marion (1993).

Management Considerations—The prescription fire window is narrow between conditions too wet to carry fire and fires that sweep through the overstory completely consuming many live understory stems 0.25 to 0.5 inch (0.6 to 1.3 cm) diameter. Among several seedbed preparation techniques, prescribed fire was judged the most risky, but it also produced the best results (Crutchfield and Trew 1961). Where pond pine is not commercially utilized, stands are often burned every 10 to 20 years to regulate fuel buildup and restore fire to the ecosystem.

One of the most important pond pine understory communities is composed of switchcane. Cane also occurs as open-grown thickets thought to have originated on abandoned Native American agricultural fields and from Native American burning practices (Platt and Brantley 1997). Early explorers often mentioned canebrakes because of their distinctive character; apparently they were once widespread ranging from the valleys of the Appalachians to the Pocosins of the coastal Plain. They have largely disappeared because of overgrazing, inappropriate fire management, or deliberate type conversion. According to Wharton (1977), river cane burns about every 5 years but reaches its maximum fuel storage of 5 to 7 tons/acre (11 to 16 t/ha) in 3 years. Regularly burned cane provides some of the most nutritious native grazing in the South (Biswell and others 1942; Hilmon and Hughes 1965b; Hughes 1966; Shepherd and others 1951). If native range improvement is an objective, fires must be frequent; otherwise shrubs will overtop the cane within a decade. Continued exclusion results in one of the most flammable fuel complexes in the South. Guidelines for using prescribed fire in the Pine Barrens can be found in Little and Moore (1945).

Mixed Mesophytic Forest

Vegetation Dynamics—The hardwood forests of the Appalachian Mountains, the Ozark Mountains, and upland hardwoods of the Coastal Plain and the Piedmont have been regularly grazed and burned from the earliest settlement times (Komarek 1982; Van Lear and Waldrop 1989). The vast Shenandoah

Valley was burned annually by Native Americans to keep it from reverting to forest (Leyburn 1962). Foley (1901) noted that fire along with logging and grazing were major determinants of the species composition at the turn of the century. In the absence of fire, a mixed mesophytic forest develops. In the old-growth stage, pine regeneration is precluded and the forest slowly moves toward a hardwood climax (Cain and Shelton 1994). Literature reviews of the effects of fire on Eastern hardwood forests are provided by Christianson (1969) and Fennell and Hutnik (1970).

Management Considerations—The use of fire in hardwood stands generally has not been recommended because of the fear of damaging stem quality and because of the danger of erosion, particularly on steep slopes (Van Lear and Waldrop 1989). This recommendation is largely based on postburn observations of wildfires, which often burn with higher intensity and severity than prescribed fires. For example, in a survey of almost 6,000 harvested upland hardwood trees nearly half had basal wounds, 97 percent of them caused by fire (Hepting and Hedgcock 1937). The incidence of decay originating in basal wounds was greater for basswood and yellow poplar than oaks. Seventy percent of the trees with basal wounds had butt rot that resulted in an average cull of more than 15 percent. But the costs of decay are greater than just reduced board feet, because fire-damaged trees take up space that could be utilized by trees of superior form (Gustafson 1946).

Reviews of fire research on Southern Appalachian and Upper Piedmont sites showed that prescribed fires had little negative impact on soil (Van Lear and Johnson 1983; Van Lear and Waldrop 1989). Although numerous questions about fire effects on soils remain unanswered, generally fires that expose mineral soil create the potential for erosion, while those that leave a portion of the forest floor do not appear to have deleterious soil or water consequences. Van Lear and others (1985) found that Piedmont sites can be harvested following a series of low-intensity prescribed burns with minimal soil loss and degradation of water quality.

Augsburger and others (1987) and Waldrop and others (1985) demonstrated that single fires have little effect on the composition of young coppice stands. Roth and Hepting (1943) and Roth and Sleeth (1939) examined numerous hardwood stands of sprout origin and found that sprouts on burned areas were forced to develop at or below the ground line, which resulted in well-anchored stems free from decay. Thor and Nichols (1974) found that both the number of stems per sprout-clump and the total number of clumps, especially oaks, increased with annual and periodic burning in comparison to unburned stands.

Low-intensity prescribed fires have also been shown to stimulate germination of yellow poplar seed (Little 1967), which can remain viable in the forest floor for more than a decade, and produce more faster growing seedlings than those on unburned sites (Shearin and others 1972). Although fire has been demonstrated to be useful in the regeneration of some mixed mesophytic forests, no references were found that advocate underburning in the management of these forests. However, research on the application of prescribed fire in this type continues. For example, a moderately intense prescribed burn was applied to a south-facing slope in the Southern Appalachians to test its effectiveness for restoring a degraded pine/hardwood community and stimulating forage production after 70 years of fire exclusion (Elliott and others 1999).

Studies conducted in the Upper Piedmont and Southern Appalachians have shown that fire can be safely used to dispose of logging debris and prepare seedbeds (Swift and others 1993; Van Lear and Waldrop 1989). For example, Sanders and others (1987) found that low-intensity dormant-season fires had little adverse effect on bole quality of mature hardwood stems. Van Lear and Danielovich (1988) noted little visible evidence of erosion on mountain slopes up to 45 percent following prescribed summer burning designed to reduce heavy logging debris and prepare the site for planting. Sanders and Van Lear (1987) showed that the judicious use of fire reduces the large amount of highly flammable fine woody material present after clearcutting by more than 90 percent. The fell-and-burn technique that gained prominence in the late 1980s can regenerate mixed pine-hardwood stands after clearcutting with minimal adverse site effects (Abercrombie and Sims 1986; Danielovich and others 1987; Phillips and Abercrombie 1987).

Northern Hardwoods

Pre-1900 Succession—Paleoecological studies suggest that Northern hardwood species such as beech, sugar maple, and birch decline following fire. Pollen and charcoal samples from Lake Wood in Acadia National Park, Maine, show that during the period about 2,000 to 6,000 BP (before present time), Northern hardwoods and hemlock were dominant. During that period, fires indicated by charcoal analysis occurred in conjunction with sharp declines in hemlock probably as a result of an insect or disease outbreak (Davis 1981). Declines of hemlock about 4,800 and 3,000 BP were followed by periods in which one or more fires burned the watershed. With the rise in importance of spruce and cedar about 2,000 BP, the incidence of fire increased with return intervals of 200 to 400 years. The abundance of maple, beech, and hemlock declined simultaneously. The watershed of Lake Wood burned in a catastrophic fire in 1947; today

it contains only one small stand (about 5 acres) of hemlock and no Northern hardwood stands. The forest is dominated by seral hardwoods (aspen, paper birch, and gray birch), northern red oak, white pine, and red pine.

Northern hardwoods such as the Bigwoods of Minnesota generally are not very flammable (Grimm 1984); fires burn as patchy, creeping ground fires. Grimm (1984) noted that “the fire regimes of deciduous forests, such as the Bigwoods, are much different from the commonly perceived model of a forest fire regime, in which fuels and fire danger increase with time and in which intense crown fires commonly cause great destruction of forest.” This is consistent with our observations in Northern hardwood stands in Maine other than at Lake Wood (table 4-5). Stands burned in 1947 currently support forests dominated by sprouts of beech and sugar maple rather than seral hardwoods (Patterson and others 1983).

A vigorous debate exists about whether Native American cutting and burning practices or climatic cooling caused shifts from Northern hardwoods to oak and pine at Crawford Lake, Ontario (Campbell and McAndrews 1995; Clark 1995; Clark and Royal 1995; McAndrews and Boyko-Diakonow 1989). Although the relative importance of Native American burning versus climate change as an influence on the larger Northern hardwood region remains open, it seems likely that changes evident in the Crawford Lake pollen profiles were partly the product of human manipulation of the forest. Clark (1995) concluded that additional studies of Native American effects on Northern hardwood forest composition are needed, but there is little evidence that Native American burning alone (without accompanying agricultural activity) was as important in Northern hardwoods as it apparently was in oak forests to the south (Abrams 1992).

Post-1900 Succession—Based on fire records from 1945 to 1976, Bormann and Likens (1979) concluded that forests in the Green and White Mountains are “among the least burnable in the ‘northern hardwood region’.” On average, only 7 to 10 acres (3 to 4 ha) burn annually per million acres (405,000 ha) on the Green Mountain and White Mountain National Forests. Fahey and Reiners (1981) calculated fire rotations in Northern hardwoods of 910 years for Maine and 770 years for New Hampshire. Current work (Patterson 1999) documents the continued trend toward less area burned (longer rotations) during the later half of the 20th century in New Hampshire and a low 20th century fire occurrence in Vermont, which has the largest representation of Northern hardwoods. Stearns (1949), who examined a virgin Northern hardwood stand in northern Wisconsin, noted that although hot slash fires “burned to the edge of the virgin stand they did not penetrate into it more than a few rods.”

Although ecologists believe fire has been a relatively unimportant ecological factor in Northern hardwoods (Bormann and Likens 1979; Fahey and Reiners 1981), they acknowledge the fact that Northern hardwoods have burned in the past, especially when adjacent stands were clearcut during the logging period and when stands accumulated fuels from blowdown (Lorimer 1977; Stearns 1949). Records suggest that modern stands have been more influenced by fire (chiefly as a result of anthropogenic fire during the period 1850 to 1950) than stands will be in the future. Even present Northern hardwood stands have been influenced to a far smaller degree by fire than have other vegetation types in the Northeast.

After the 1947 fire in Acadia National Park, beech and sugar maple stands have returned to their original stand composition more rapidly than any other

Table 4-5—Average basal area (sq ft/acre) by species for Mt. Desert Island northern hardwood stands burned in 1947 and before 1880 (Patterson 1999).

Species	Burned in 1947		Burned before 1880	
	Sample year		Sample year	
	1980	1992	1980	1992
Red spruce	—	0.1	0.6	1.6
Hemlock	0.1	0.1	0.4	—
Paper birch	4.8	4.3	4.0	4.2
Yellow birch	0.1	0.3	0.1	0.7
Red maple	0.3	1.2	0.4	0.9
Sugar maple	4.4	3.1	7.0	5.0
White ash	0.1	—	1.5	1.1
American beech	11.7	15.0	9.6	9.2
Striped maple	0.5	1.6	0.9	2.2
Bigtooth maple	0.7	1.5	0.2	0.4
Others	0.5	0.2	0.3	0.2
Total	23.2	27.4	25.0	25.5

forest types (table 4-5) (Patterson 1999; Patterson and others 1983). Although Northern hardwood species are widely viewed as having little resistance to fire, maple and birch sprout vigorously from the stump; beech suckers from the root system as vigorously as aspen (Fowells 1965). This capacity for rapid vegetative reproduction appears to limit invasion of Northern hardwoods by seral aspen, paper birch, and gray birch. These species are short lived and cannot persist in competition with beech, maple, and yellow birch in the absence of frequent, stand-replacing disturbances (Patterson and others 1983). The present dominance of white birch on some sites in the White Mountains is probably more a reflection of increased incidence of fire and logging in the 1800s than it is an indicator of the long-term importance of fire on the landscape.

Management Considerations—As management shifts toward longer harvest rotations and reduced volume removal, Northern hardwoods will likely regain their historic position of importance on mesic, fire-protected sites in the Northeast. Northern hardwoods are susceptible to fire (Swan 1970). Where Northern hardwoods mix with conifers including hemlock, white pine, red spruce, and balsam fir, fires are likely to be more common, especially in the wake of catastrophic wind storms (Foster 1988; Lorimer 1977; Stearns 1949). If climate warms and incidence of fire is reduced, Northern hardwoods may return to some sites at the present hardwood-boreal forest boundary while giving way to transition hardwood-conifers to the south. However, the increased presence of human ignition sources may alter fire-vegetation relationships evident in presettlement forests.

Bottomland Hardwoods

Vegetation Dynamics—In young pole size stands, fires often result in basal wounds. Although these wounds often heal over, internal decay continues with decay height closely related to time since fire. Kaufert (1933) estimated that 90 to 95 percent of the decay in merchantable Southern bottomland hardwood stands was the result of past fires. When mature oaks die in areas protected from fire, species such as red maple, American elm, and green ash tend to replace them (Abrams 1992). Lotan and others (1981) stated that because the elm-ash forest is moderately fire-prone, prescribed fire should be tested for its ability to control insect and disease pests and unwanted understory. Keep in mind that most bottomland hardwoods, even large ones, are sensitive to fire. Low-intensity fires appear benign at first glance, but the cambium has been damaged and incipient decay begins even though the bark remains intact for several years after fire.

Stand-Replacement Fire Regimes

Major Vegetation Types

Vegetation types in the Eastern United States represented by stand-replacement fire regimes, where fire typically kills more than 80 percent of the overstory, include prairie, wet grassland, and portions of the oak-gum-cypress (bay forests) FRES ecosystem types (table 4-1). The conifer cover types include sand pine, Table Mountain pine, Atlantic white-cedar, and spruce-fir. Pocosins without a significant component of pond pine are also a stand-replacement fire regime type.

Wet Grasslands

Kuchler (1964) recognized two major regions of herbaceous wetlands in the Eastern United States, exclusive of the Everglades of southern Florida (see chapter 7). These regions include the northern cordgrass prairie, which extends along the Atlantic coast from Maine to southern Florida, and the southern cordgrass prairie, which spans the Gulf of Mexico from southern Florida to southern Texas. Numerous marshes, some quite extensive, occur in inland areas in the Eastern United States, and many of these possess characteristics similar to freshwater coastal marshes.

It is convenient to distinguish salt and brackish from oligohaline (tolerant of moderate salinities) and fresh marshes because of consistent differences in species composition and fire behavior. Along the Atlantic seaboard, salt marshes can be further subdivided into the New England group and the Coastal Plain group (Mitsch and Gosselink 1993). Salt marshes of the New England group extend from Maine to New Jersey and are built mainly on marine sediments and marsh peat, with relatively little sediment discharge from distributaries. Salt marshes of the Coastal Plain group extend southward from New Jersey to Florida, where they are replaced by Mangrove forests at the southern tip of Florida.

Salt and brackish marshes are largely dominated by species of cordgrass and rush. The regularly flooded, tidal salt marshes in the Eastern United States are dominated almost entirely by smooth cordgrass. Regularly flooded areas typically are referred to as low salt marshes to distinguish them from high salt marshes, which occur inland from the low salt marshes, are less frequently flooded, and often contain more stressful soil conditions due to stagnation and evaporative concentration of salts (Mitsch and Gosselink 1993). Low salt marshes reach their greatest extent in South Carolina, Georgia, and along the Gulf of Mexico (Teal

1986). High salt marshes can be dominated by several species such as smooth cordgrass, needlegrass rush, pickleweed species, inland saltgrass, saltmeadow cordgrass, and saltmeadow rush. Along the Texas coast, high salt marsh can include extensive stands of gulf cordgrass, which is also the characteristic dominant of salty prairie, an upland community type. In brackish areas, salt marsh species yield dominance to species of slightly less salt tolerance, and a greater variety of both dominant and subordinate species can be found (Gosselink 1984). In addition to a shift in the herbaceous layer, brackish marshes often include woody species, especially eastern baccharis and bigleaf sumpweed. A more detailed discussion of the geographic variations in salt marsh geomorphology and vegetation can be found in Mitsch and Gosselink (1993).

Coastal marshes that receive freshwater and are removed from the direct influence of salt water form the inner band of coastal marshes. These marshes reach their greatest extent along the middle and southern Atlantic Coast and along the northern Gulf Coast. The Atlantic Coast freshwater marshes include about 405,200 acres (164,000 ha), while those in the northern Gulf of Mexico cover about 1,156,400 acres (468,000 ha). Generally, fresh and oligohaline wetlands occur where salinities are less than 5 ppt, but wetland types are more easily recognized by the known salinity tolerances of the vegetation rather than the average soil or water salinity (Brewer and Grace 1990). Many plant associations exist because of the high diversity of species found in fresh and oligohaline marshes. The lowest fresh marshes are characterized by plants that root in relatively deep water, such as species of pond-lily, waterlily, wildrice, and cutgrass. Along the Atlantic Coast, tidal fresh marshes include both annual streamside associations and perennial associations of green arrow arum, pickerelweed, arrowhead species, and cattail species. In fresh marshes of the Gulf Coast, bulltongue arrowhead, maidencane, spikerush species, and numerous sedge and forb species are predominant.

Prairie

The prairie ecosystem in the United States, referred to by many as the tallgrass prairie, forms a rough triangle from the Minnesota and North Dakota border south to the Texas Gulf Coast and eastward into northern Indiana (Reichman 1987). It is dominated by big bluestem, Indiangrass, and switchgrass. Drier sites are dominated by little bluestem, and wet, lowland sites are often dominated by prairie cordgrass. Within this grass matrix are more than 250 forb species (Freeman 1998). The local species composition at any one place is dependent on burn history, grazing history, soils, aspect, and topographic position. In

Indiana, Illinois, and Wisconsin only 0.1 percent of this ecosystem remains. The Flint Hills region of Kansas has the most remaining prairie, 3 million acres (1.2 million ha), which is only 17 percent of the presettlement prairie in Kansas (Samson and Knopf 1994). The prairies that do remain outside of the Flint Hills region are widely scattered and often smaller than 1.2 acres (0.5 ha) (Betz and Lamp 1989). The tallgrass prairie is one of the youngest ecosystems in North America. Much of the region was glaciated only 10,000 years ago. This region has few endemic species, so most plant and animal species have migrated into this region from neighboring ecosystems (Risser and others 1981).

Portions of the tallgrass prairie consist of oak savannas and glades or barrens. Herbaceous species found in savannas are a mixture of forest and prairie species (Curtis 1959); there are no endemic savanna species. In wetter periods, or periods with reduced fire frequency, savannas can be converted to forests. In drier years or with shortened fire intervals, savannas can be converted to grasslands. Whether savannas are stable ecosystems or simply an unstable continuum between closed canopy forest and open grasslands is debatable (Nuzzo 1986). Today, Nuzzo (1986) estimates that only 0.02 percent of presettlement savanna survives and that the largest savannas are only about 50 acres (20 ha).

Glades or barrens are patches of prairie within a forest matrix. The barrens region stretches across Missouri, Tennessee, Kentucky, southern Illinois, Indiana, and Ohio (Baskin and Baskin 1978). These grasslands occur only on very dry, shallow soils, which are usually found on south- or west-facing slopes. Anderson and Schwegman (1971) stated that barrens are “degraded forests that had been invaded by prairie plants as a result of fire” and that in the absence of fire the areas quickly revert to forest. However, Wade and Menges (1987) stated that these glades don’t support woody vegetation except for the shallow rooted eastern redcedar; thus, they are often termed cedar glades (Baskin and Baskin 1978). If fire is excluded for long periods, trees encroach around the edges of glades and reduce their size.

Bay Forests

This ecosystem type occurs primarily in North and South Carolina but can be found along the Atlantic Coast from Virginia to Alabama. Carolina bays and pocosins without an overstory of pine or Atlantic white-cedar are the major vegetation types. Much of the original type contained a merchantable overstory that was harvested, thereby altering the fire cycle. This type is characterized by a dense tangle of evergreen and deciduous shrubs and vines (Richardson

and Gibbons 1993). Carolina bays are swamps dominated by bay species. Numerous species of special concern including several Federal and State listed species occur in this vegetation type.

Conifers

Sand Pine—Two varieties of sand pine, Choctawhatchee and Ocala, are recognized here because their fire ecology requires different management. The natural range of Choctawhatchee sand pine is confined to the panhandle of Florida and Baldwin County, Alabama (Brendemuehl 1990). It originally was restricted to the Gulf shoreline (islands and dunes) where fire was infrequent (Outcalt 1997). The Ocala variety has serotinous cones and is confined to the central Florida ridge and on old sand dunes down both coasts from central to southern Florida. It is easily distinguished from the Choctawhatchee variety, which generally lacks serotinous cones.

Table Mountain Pine—This serotinous cone species is endemic to the Appalachians from Pennsylvania to northeastern Georgia, with local populations in New Jersey and Delaware (Little 1978). According to Sternitzke and Nelson (1970), about 90 percent of the standing inventory is in West Virginia, Virginia, and North Carolina. Table mountain pine forms even-aged pure stands or shares dominance with pitch pine. Common hardwood associates include red maple, blackgum, sourwood, chestnut oak, and scarlet oak (Della-Bianca 1990), which eventually dominate these sites in the absence of fire. A dense shrub layer of mountain-laurel, which will burn within a week of good drying conditions during the dormant season, is often present along with other ericaceous shrubs such as blueberries and huckleberries.

Spruce-Fir—This is a high-elevation forest type of the Appalachians and is one of the rarest and most threatened ecosystems in the South (White and others 1993). In the Southern and Central Appalachians, stands comprise red spruce, the endemic Fraser fir, and balsam fir. In the Northeast, red and white spruces and balsam fir make up this forest type.

Atlantic White-cedar—This species tends to form pure stands throughout a narrow coastal belt from southern Maine to northern Florida (Little 1959) and westward to the Mississippi (Little 1978). However, its distribution is spotty because it avoids substrates underlain with clay (Little 1950). It requires moist sites with a long hydroperiod but without stagnant water, generally in swamps with organic soils.

Fire Regime Characteristics

Wet Grasslands—Much of the coastal region of the Southern United States, from Virginia to Texas, is

characterized by a presettlement fire frequency of 1 to 3 years (Frost 1995). Coastal marsh landscapes are typically extensive, a factor that aids in the propagation of an individual fire. Natural barriers to fire spread are relatively common and vary from wide river channels to small stream channels and narrow animal trails. Depending on the fuel and wind speeds, fires may either bridge small to moderate-sized natural breaks or be stopped by them. Thus, the extent of natural fires varies greatly as does the ease of accomplishing a prescribed burn. Lightning-strike fires are thought to be common in coastal wetlands (Frost 1995), and often fire from the adjacent upland can spread into the marsh. Spontaneous combustion has been reported to occur in coastal marshes (Viosca 1931), though how frequently it happens is largely unknown.

Away from the coastal influence of a persistently high water table, peat fires can be common during prolonged dry periods and can represent a substantially more severe fire, leading to loss of substrate and protracted subterranean burning. While such fires may not be the norm for coastal marshes, they can be important under some circumstances (Hungerford and others 1995). For all fires, coastal or inland, groundwater levels are important for both the behavior of the fire and its effects on vegetation and soil (Bacchus 1995).

Prairie—Historically, Native Americans contributed to the creation and maintenance of the tallgrass prairie ecosystem by frequently burning these ecosystems, which controlled woody vegetation and maintained dominance by herbaceous plants. In the Eastern tallgrass prairie, Native Americans were probably a far more important source of ignition than lightning. With grasses remaining green through late summer and a low incidence of dry lightning storms, lightning-caused fires were probably relatively infrequent.

Few studies of the pre-Euro-American tallgrass prairie have been conducted. Most existing data are primarily anecdotal, based on widely scattered accounts of early explorers. Existing data on burn frequency in the tallgrass prairie come from studying tree rings on the prairie-forest margin. In Missouri, Guyette and McGinnes (1982) determined that fires occurred every 3.2 years prior to 1870. After 1870, the average fire return-interval increased to 22 years. On the Mark Twain National Forest, Guyette and Cutter (1991) determined that from 1710 to 1810, fires occurred on average every 4.3 years and that severe fires (fire scars on three or more trees) occurred every 11 years. After 1810 fires occurred every 6.4 years, and no fire scarred more than two trees. But fire scar studies are typically conservative and tend to underestimate fire frequency, which could be the case here because historical accounts reported annual burning in the tallgrass prairie

(Pyne 1997). After Euro-American settlement, fires were less frequent and burned smaller areas. The reduction in fire frequency resulted in replacement of large areas of grasslands by woodlands (Beilmann and Brenner 1951; Muir 1965; Pyne 1997).

Some notion of the seasonality of historic fires can be learned from early explorers and missionaries dating back to the late 1600s. According to Pyne (1997), Wells stated in 1819 that fires in western Pennsylvania were set by Native Americans at the end of the Indian summer, presumably October; Michaux observed in 1805 that fires occurred in March or April in Kentucky; and James reported in 1819 that fires in Missouri usually occurred in the fall. In Illinois, McClain and Elzinga (1994) reported that historically almost all fires were ignited during the Indian summer, late October to early November. Euro-Americans continued the burning practices they learned from Native Americans until early in the 20th century when these historic fire patterns were altered through fire suppression, planting of cool season grasses, and the use of prescribed burning concentrated in the spring to improve forage for livestock. It appears from these historical accounts that the season when fires were common varied regionally and through time as a result of the cultural practices of the people living in a particular area.

In addition to fire, bison and other large grazers influenced the tallgrass prairie. Bison were present throughout the tallgrass region (McClain and Elzinga 1994); thus periodic grazing was a significant influence on plant communities (fig. 4-20). Bison prefer burned to unburned grassland for grazing during the growing season and can contribute to the pattern of burning in prairie (Vinton and others 1993). The variability of grazing by bison may have created variability in the patchiness of fuels and severity of subsequent fires. The effects of grazers in tallgrass prairie plant communities are reviewed by Hartnett and others (1996), Hartnett and Fay (1998), Howe (1999), and Knapp and others (1999).

Bay Forests—This type now burns on about a 20 to 100 year cycle, but uncertainty exists about the historic fire frequency. Wharton (1977) stated that 50 to 150 years are required for mature bay forests to develop. McKevlin (1996) believes fire frequency is probably less now than it was 200 years ago in spite of lowered water tables. The presence of charcoal lenses at various depths in the underlying organic soil is evidence of extensive fires in the past (Dolman and Buol 1967).

Conifers—The fire cycle for Ocala **sand pine** corresponds roughly to stand longevity, which is 30 to 60 years (Christensen 1981). The historic fire frequency for the Choctawhatchee variety is unknown but lightning fires were rare. This variety grows in pure stands,

Figure 4-20—Grazers are attracted to freshly burned areas because of increased forage quality, Konza Prairie Biological Station, Riley County Kansas. Fire management can control the distribution of grazers on the landscape. Photo by Greg Hoch.

directly inland from the beach, separated from more pyrophilic vegetation types by wet intradune swales and sparse dune vegetation.

Little is known about the historical fire frequency in **Table Mountain pine**. Barden and Woods (1974) found that fires in Table Mountain pine were more frequent, more intense, and probably larger earlier this century. Between about 1800 and 1944, the fire interval in sampled stands averaged 10 to 12 years. Now the fire return interval is between 7 and 70 years with an average of 40 years based on USDA Forest Service records. A commonly accepted hypothesis is that the fire practices of the large Native American population inhabiting the Southern Appalachians exposed both Table Mountain and pitch pine to frequent understory burns keeping the stands open, thereby ensuring successful regeneration after the occasional stand-replacement fire. Zobel (1969) suggested an evolutionary link between fire and Table Mountain pine because of its fire adaptations.

Fires rarely occurred in **spruce-fir** forests prior to Euro-American settlement. Two relatively recent instances in Maine were the 4 days in October 1947 when about 7,000 acres (2,830 ha), including spruce-fir,

burned, and the summer drought fire that involved Mount Katahdin in the early 1990s. Before Euro-Americans harvested **Atlantic white-cedar**, this prized species was mostly perpetuated by major disturbances, probably crown fire that occurred at 25 to 300 year intervals. Mature cones can develop by age three in open stands, which supports the crown fire hypothesis.

Fuels and Fire Behavior

Wet Grasslands—Coastal marshes typically support high fine fuel loadings. Estimates of standing biomass range from 4 to 18 tons/acre (10 to 40 t/ha) (Gosselink 1984; Odum and others 1984) and higher (Gough and others 1994). Hackney and de la Cruz (1978) have reported that for some species, full recovery of standing biomass to preburn levels can occur in a single growing season, while it may take several years for other species. Informal observations of fire behavior indicate that marsh fires are generally consistent with other grassland fires in the Eastern United States. Rates of lateral spread vary with wind speeds and can exceed 3 feet/second (1 m/s). Flame heights can vary from less than 3.3 feet (1 m) for short or sparse vegetation and up to 13 feet (4 m) for dense or tall vegetation (fig. 4-21). In typical areas of fine fuels, marsh fires

produce fewer flying embers than shrubland or forest fires and are generally less likely to produce spot fires.

Coastal marshes typically contain large quantities of herbaceous vegetation and are considered highly flammable. But not all marsh types and plant species are equally conducive to propagating a fire. The vegetation of salt and brackish marshes is relatively similar throughout the coastal region of the Eastern United States, with species of cordgrass, rush, and saltgrass as typical dominants. The cordgrass species, which are generally the most widely represented group throughout coastal salt and brackish marshes, tend to be quite flammable. Species such as saltmeadow cordgrass and gulf cordgrass can burn readily while tissues are green and are capable of burning more than once in a single growing season. All of the cordgrass communities are capable of carrying fire over standing water.

Flammability of vegetation throughout fresh and oligohaline marshes can be highly variable due to the considerable plant diversity (Gough and others 1994). In general, grasses support much more intense and continuous fires than do forb and sedge associations. Some exceptions to this include dense stands of sawgrass and cattail, which are capable of supporting extensive fires. Common species that generally provide good fuels

Figure 4-21—Headfires in sawgrass behave similarly in other Eastern wet grasslands, Everglades National Park. Photo by Wayne Adkins.

include reed, maidencane, and switchgrass. Dominant species that represent poor fuels include bulltongue arrowhead, spikerush species, alligatorweed, hydrocotyle species, pickerelweed, and green arrow arum. Generally, grass-dominated associations burn more readily than those dominated by sedges or forbs. Among grass-dominated associations, fresh and oligohaline marshes (for example, panicums) tend not to burn as reliably as those in the brackish and salt marshes (Ford and Grace 1998a). Forb associations, such as the extensive bulltongue arrowhead community of the lower Mississippi River wetlands, typically provide poor fuel for fires during the dormant season when plant tissues have decomposed and fuel is sparse. In other forb-dominated plant associations, propagation of a fire may only be successful during the dormant season when aboveground tissues have senesced.

The presence of woody plants in coastal marshes can alter fire behavior substantially in some cases. Where the woody plant component is high, reduced airflow to fine fuels may reduce the completeness of the burn and the rate of fire spread. Nonetheless, fire generally kills the aboveground portions of these woody species (Scifres and Hamilton 1993). Succession to woody associations in fresh marshes is common, particularly where water depths are not excessive and substrates are firm. A heavy dominance by species such as willow, maple, cypress, tupelo, cedar, Chinese tallow, and bayberry can substantially reduce herbaceous fuels. These communities are likely to burn only under very dry conditions.

Prairie—Early explorers and settlers described abundant grasslands, prairies, savannas, and open woodlands with grass and herbaceous understories throughout the Eastern United States. The exact characteristics of tallgrass prairie such as height, loading, and percent cover are unknown but can be estimated from historical accounts. Grasses were 3 to 6 feet (1 to 2 m) high; they were often described as tall as a man on horseback. Percent cover was substantial (>50 percent) over hundreds of square miles. From these characteristics, loadings are conservatively estimated to range from 2 to 5 tons/acre (4.5 to 11.0 t/ha).

Fuel loadings ranged from 1.1 tons/acre (2.5 t/ha) for sparse communities to 3.4 tons/acre (7.6 t/ha) for abundant communities in fuel models developed for fire behavior modeling (Reinhardt and others 1997). These loadings were based on estimates of current production (Garrison and others 1977) and accumulated thatch or litter. Flame lengths of 12 feet (3.6 m) could be expected assuming these loadings, 6 percent fuel moisture content, and windspeed of 20 mph (32 km/hr) (Rothermel 1983). Thus, historical prairie fires probably burned much of the time with flame lengths of 8 to 15 feet (2.4 to 3.6 m), too hot for direct frontal attack with hand tools.

Bay Forests—Forest floor and downed woody fuels averaged 10 tons/acre (22 t/ha) in the Piedmont of North Carolina (Albrecht and Mattson 1977). In the Great Dismal Swamp in Virginia, Day (1979) found loadings of accumulated dead and live understory fuels (< 1 inch diameter) in a mixed hardwood stand of 9.7 tons/acre (21.7 t/ha) and on a maple-gum site of 15.6 tons/acre (35.1 t/ha). Also, see pond pine fuels and fire behavior in the Mixed Fire Regime section.

Conifers—**Sand pine** needles are short and form a flat mat on the forest floor that burns poorly and supports creeping fires. Needle-drape is not a flammability problem in either variety. Mature stands average about 10 to 15 tons/acre (22 to 34 t/ha) of available fuel composed mainly of live understory biomass (Custer and Thorsen 1996). Lightning fires are common, typically small, low-intensity creeping fires that go out at night when the humidity rises. The primary ground fuel is deer moss, which can produce flame lengths of 2 to 3 feet (<1 m) when dry, but when humidity is high, the moss absorbs moisture from the air and will not even smolder. The Ocala variety often supports a well-developed understory of scrub oaks, ericaceous shrubs, and rosemary that will burn intensely when dry and pushed by a strong wind. This variety also exhibits a “varnish stage” when the needles unexplainably exude a sap-like substance that is exceedingly flammable (Hough 1973). This condition is usually observed in the fall and occurrences can be decades apart. The Ocala fuel complex typically burns with intense fires that almost always enter the stand from more pyrogenic adjacent communities (fig. 4-22). The fastest spreading wildfire recorded in the United States occurred in this fuel type; it covered 35,000 acres (14,170 ha) in 4 hours with a spread rate of 6 mph.

Under **Atlantic white-cedar** stands in the Great Dismal Swamp of Virginia, Day (1979) found average loadings of 1.8 tons/acre (4.0 t/ha) for the litter layer, 1.2 tons/acre (2.7 t/ha) for woody fuels <0.75 inch (2 cm) diameter, and 22.4 tons/acre (50 t/ha) for woody fuels >0.75 inch (which included stumps as well as logs).

Postfire Plant Communities

Salt and Brackish Marshes

Pre- and Post-1900 Succession—Many coastal marshes are dependent on fires that are lethal to aboveground tissues and that reduce or eliminate woody plants. Woody plants can, however, be excluded from an area by excess salinity. Saline and hypersaline soil conditions generally preclude most native woody species in both coastal and inland wetlands throughout the temperate zone, with the exception of salt-tolerant mangroves, which are restricted to subtropical-tropical latitudes in southern Florida (Mitsch

Figure 4-22—Stand replacement burn in Ocala variety sand pine on the Ocala National Forest, Florida. Photo by George Custer, 1993.

and Gosselink 1993). Marshes formed on unconsolidated or floatant substrates are also typically unsuitable for the long-term success of trees even in the absence of fire (Doyle 1995). In some situations, woody succession may be precluded by herbivores. For example, in much of southern Louisiana wild populations of nutria are believed to prevent successful reestablishment of baldcypress (Connor and Toliver 1987). The herbaceous communities that develop in marshes, as a result of fire, edaphic influences, or herbivores, tend to be readily flammable and are well adapted to frequent fires.

Despite the frequent presence of standing water, fire is able to propagate in both low and high salt marsh and in brackish vegetation. As a result, these systems are frequently burned, both naturally and with prescription. Postfire succession patterns vary somewhat with salinity and preexisting vegetation. In low salt marshes, little species replacement occurs and smooth cordgrass typically retains dominance. Thus, the main

effect on vegetation is a replacement of old tissues with younger tissues that are more palatable to wildlife species. In high salt marshes, fire causes few long-term shifts in vegetation, although it may provide a brief period when dominance by cordgrass is reduced and interstitial species increase. Successional patterns are more pronounced in brackish marshes following fire. In areas of the central and western Gulf coast, succession from herbaceous dominance to dominance by eastern baccharis takes place over several years. Frequent fires in these systems keep woody species from dominating. On a shorter time span, fire in brackish marshes reduces dominance by cordgrass and rush species temporarily and favors earlier successional species such as chairmaker's bullrush (Ford and Grace 1998a).

Management Considerations—According to Nyman and Chabreck (1995), the frequency of intentional fires increased around 1910 as burning in coastal marshes became a more common practice for promoting wildlife populations and reducing the hazards of wildfires. Today, prescribed fire is commonly and frequently used in salt and brackish marshes to enhance productivity (Hackney and de la Cruz 1981), manage food sources for wildlife and cattle, reduce plant cover, reduce fuel loadings, and eliminate woody species such as baccharis (Chabreck 1988).

In the absence of fire, succession to woody dominance can take place in only a few years. Where the control of woody plant succession is of highest priority, growing-season burns approximately every 3 years are the most effective. Observations indicate that baccharis-dominated systems remain flammable, in contrast to those overtaken by the introduced exotic, Chinese tallow. This species can greatly reduce fire intensity and fire propagation in dense stands (Grace 1998). Only frequent fires are likely to effectively prevent its invasion into wetlands. Once Chinese tallow exceeds a certain density, it typically becomes nonflammable and acts as a firebreak. Once this density threshold is reached, herbicides or mechanical means will be required for its removal.

Waterfowl and mammals alike generally prefer early successional plant species as well as the younger tissues of resprouting plants. Some fire-promoted species such as chairmaker's bullrush are considered of exceptionally high value to muskrat (*Ondatra zibethicus*), nutria (*Myocaster coypus*), and snow geese (*Chen caerulescens*). In areas where burning is commonly used to promote wildlife populations, burns may be conducted in the fall and winter to provide a steady supply of young tissues throughout the winter. For cattle grazing, burning is often recommended as a method of temporarily increasing dietary crude protein and forage quality (Angell and others 1986; McAtee and others 1979).

Marsh fires can be classified as cover burns, root burns, and peat burns (Lynch 1941; O'Neil 1949). Water levels control the depth of influence of fire. Thus, proximity to the water table, tidal conditions, and drought cycles can determine the severity of impact to belowground plant parts and to substrate. While more common in inland areas such as the Everglades, peat burns have been reported in coastal wetlands along the Gulf of Mexico (Hoffpauir 1968; Lynch 1941). During dry periods it may be possible to create fires that could substantially damage plant roots. Documented success in using such burns to control plant species, however, is lacking (Nyman and Chabreck 1995).

Prescribed fire for promoting desired wildlife forage species such as chairmaker's bullrush appears to be more successful when conducted during the fall or winter. Spring burns are believed to damage the regrowth of this species and lead to more persistent dominance by saltmeadow cordgrass (Chabreck 1981). Fall and winter burns may be used to avoid destroying nests or killing young wildlife (Nyman and Chabreck 1995). Fires aimed at promoting nutria and many other species are often limited in size to produce a landscape mosaic of burned and unburned habitat (Kinler and others 1987). Postburn water levels can substantially influence the effects of fire on vegetation. When stubble is submersed for an extended period, complete death can occur for many wetland species (Herndon and others 1991; Sale and Wetzel 1983). See Chabreck (1988) for more information on the use of fire to manage wildlife, and Kirby and others (1988) for an extensive bibliography of literature dealing with fire effects on wildlife.

Avoiding use of fire to favor wildlife may be wise under certain circumstances. For example, in the Mississippi delta, geologic subsidence rates have contributed to extremely high rates of marsh loss because coastal areas have subsided faster than accretion occurs. In this situation, the feeding activities of nutria and other mammals can contribute to habitat loss (Ford and Grace 1998b). Nyman and Chabreck (1995) noted that the potential exists for deleterious effects of marsh burning in this region. Hypothetically, fire could accelerate rates of wetland loss through the removal of organic matter that might otherwise contribute to sediment accretion and through the promotion of wildlife populations that lead to consumption of vegetation. At present, experimental evaluation of this hypothesis is lacking.

Another factor is the possibly deleterious grazing by snow geese. Currently, excessive numbers of snow geese are causing extensive damage to the northern wetlands where they breed and they are also known to cause extensive eat-outs of southern coastal wetlands.

There is no evidence at present that burning is significantly affecting their population. However, burning of coastal wetlands can attract wintering snow geese to recently burned areas and increase the potential for localized damage. Finally, because of the important role of marshes as sources of organic matter for estuarine food webs, high fire frequencies are not necessarily ideal for near-shore systems (Hackney and de la Cruz 1978; Nyman and Chabreck 1995). A more complete discussion of salt marsh fire ecology can be found in Lynch (1941), Bendell (1974), Daiber (1974), Frost (1995), Nyman and Chabreck (1995).

Fresh and Oligohaline Marshes

Pre- and Post-1900 Succession—Various successional sequences are found from fresh marshes to forested wetlands for the most inland of the fresh marshes. Fresh and oligohaline wetlands may succeed to dominance by baldcypress, swamp tupelo, water tupelo, and red maple as well as to Chinese tallow (Frost 1995). A number of factors may impede woody plant development including unconsolidated substrate, scouring by waves, and periodic fires. Fire-driven successions in freshwater coastal marshes are poorly documented. Evidence suggests that as with brackish marshes, fire releases a diversity of early successional species that are more palatable to wildlife (Ford and Grace 1998a). Succession of the herbaceous communities in fresh and oligohaline marshes tends to be rapid as it is in salt and brackish marshes. Preburn vegetation can regain its dominance in a few years. Van Arman and Goodrick (1979) reported that 6 months after prescribed burning a Florida freshwater marsh, vegetative recovery was almost complete, and total numbers of animal species and individuals were significantly higher in the burned area than in the adjacent unburned marsh. Increases in these macroinvertebrates and smaller fish populations at the lower end of the food chain suggest that these increases potentially could be passed on up the scale. See Ewel (1995) and Frost (1995) for a more detailed consideration of the role of fire in regulating succession in forested freshwater wetlands.

An increasingly common successional pattern in fresh marshes is due to invasion of Chinese tallow, which has limited tolerance to salinity and is largely confined to fresh and oligohaline wetlands. Evidence indicates that when Chinese tallow invades a wetland or upland grassland it causes a shift from a grass-dominated herbaceous layer to a sparse forb-dominated layer that is much less capable of carrying a fire. As a result, stands of Chinese tallow act as firebreaks. Below some minimum stand density, fire can be used to effectively control Chinese tallow as long as adequate fuel remains (Grace 1998).

Management Considerations—The use of prescribed fire in coastal fresh marshes is much less extensive than in salt and brackish marshes (Chabreck 1988). Fires in salt and brackish marshes, however, often spread into fresh marsh areas, resulting in a relatively frequent burn regime for associations that will propagate fire. Prescribed burning in fresh marshes is more likely to be used for fuel reduction and to control woody plants such as wax myrtle, thinleaf alder, and Chinese tallow than to promote wildlife populations. Nonetheless, when wildlife or cattle production is the goal, the same management recommendations apply to fresh marshes as described previously for brackish and salt marshes.

Prairie

Vegetation Dynamics—A primary effect of fire in tallgrass prairie ecosystems is the control of invading woody species (Anderson and Van Valkenburg 1977; Wade and Menges 1987). The rapid conversion from prairie to forest with the removal of fire was noted in the early 1800s. Muir (1965) observed in Wisconsin that as soon as sufficient firebreaks were created, a thick oak forest invaded the prairie. In 1822, botanist Edwin James reported, “Whenever the dominion of man is sufficiently established in these vast plains, to prevent the annual ravages of fire, trees will spring up” (Pyne 1997). One of the most aggressive woody species in the prairie is eastern redcedar. In the absence of fire this species could quickly become the dominant tree over much of the Ozark region (Beilmann and Brenner 1951). Cedar forests now occupy 6.4 million acres (2.6 million ha) in five Midwestern States, an increase of 113 percent during the last three decades (Schmidt and Leatherberry 1995). In as little as 30 years after fire, a treeless pasture can be converted to a closed canopy cedar forest (Hoch and Briggs 1999).

In savannas, frequent fires tend to be of low intensity, do not kill overstory trees, and create an open understory. Infrequent fires are more intense due to litter accumulation, can kill overstory trees, and promote vigorous sprouting of woody species, often creating a thicket. Fires every 2 to 3 years held woody canopy at a constant level (Faber-Langendon and Davis 1995). Generally, more frequent fires reduced tree canopy while less frequent fires increased tree canopy. Faber-Langendon and Davis (1995) suggested that a 4 year fire interval might be best for controlling tree spread because at this interval fires would burn more intensely than annual or biennial fires.

Fire frequency affects species differently. Generally, big bluestem shows no response to time since fire, while little bluestem, Indiangrass, and switchgrass all decrease with time since fire (Collins and others 1995). Gibson (1988) found that perennial forbs and cool-season grasses increased with time since fire, while

annual forbs and warm-season grasses decreased. Annual or frequent burning tends to decrease herbaceous plant diversity in tallgrass prairie. Knapp and others (1999) found that annually burned areas had lower species richness than unburned areas and areas burned every 4 years. Collins and others (1995) found that species richness increases for 7 to 8 years after burning, and that time since burning was the primary agent in determining variation in species composition. Gibson (1988) argued that burning every 4 years might be the best strategy for maintaining maximum diversity (fig. 4-23). In annually burned areas fewer species can become established. In unburned areas litter accumulation creates too much shade for many species. Burning every 3 to 4 years ensures that most of the species present will have at least one “optimal” year for growth and reproduction. Collins (1987) showed that a combination of burning and grazing resulted in higher plant species diversity than burning or grazing alone.

Generally, net primary production increases the growing season following burning (fig. 4-24). If a prairie remains unburned, detritus accumulates that shades the soil, especially at the beginning of the growing season, and limits production (Knapp and Seastedt 1986; Seastedt and Knapp 1993). However, the decomposing detritus adds nitrogen to the soil, and the detrital layer insulates the soil from drying. Researchers have theorized that long-term annual burning would reduce soil nitrogen levels and lead to decreased productivity. However, even after 20 years of annual burning at Konza Prairie, Kansas, productivity has not decreased (Blair and others 1998) probably because a large pool of soil nitrogen buffers the system. Only now are declines in soil nitrogen becoming evident in these annually burned grasslands. The influence of burning on net primary production also depends on interactions with other factors such as drought. In drought years, fire can decrease net primary production (Briggs and Knapp 1995). Following fire, higher levels of net primary production will occur on a long-term unburned area than on annually burned areas, primarily due to the accumulation of soil nitrogen.

Seasonality Influences—Seasonality of fire can have a dramatic effect on species composition and diversity (Platt and others 1988a). Henderson and others (1983) found that early spring burning did not affect cool season grasses while late spring burning reduced flowering up to 70 percent. In contrast, burning in the fall or spring increased flowering in the warm season grasses over flowering in unburned areas; late spring burning treatments showed the greatest flowering activity. Henderson (1992a) determined that late spring burning significantly reduced diversity compared to early spring or fall burning due to

Figure 4-23—Periodic fires increase the diversity of tallgrass prairie plants, Smith Pioneer Cemetery, Vermilion County, Indiana. In its eastern range, the tallgrass prairie is found in isolated “remnant” prairies, old cemeteries, and along railroads. Many are smaller than 1 or 2 acres (0.5 ha) and surrounded by agricultural fields.

Figure 4-24—Productivity of all plants, especially the grasses, increases following fire, Smith Pioneer Cemetery, Vermilion County, Indiana. In the Eastern tallgrass region, dominant grasses such as big bluestem pictured here, could reach heights of 11 feet (3.4 m) or greater. Photo by Greg Hoch.

removal of cool season grasses and several mid- and late-season flowering forb species. Prairie violet and blue-eyed grass, early flowering species prone to damage by spring burning, were not lost. This study also suggested that burning in the fall might benefit prairie violet, blue-eyed grass, and sky blue aster. Henderson (1992b) found that pasque flower was favored by early spring fires that occurred before bud emergence. However, this pattern was reversed in years having high rabbit herbivory or late frosts. Areas burned early in the spring were preferentially grazed by rabbits. In years with late frost the thatch from the previous year seemed to insulate the emerging buds from late frosts.

Howe (1994, 1995) determined that species richness was higher on plots burned in July than on plots burned in March or unburned plots in a restored prairie. Two species, blackeyed Susan and annual fleabane, were found only in the summer burn plots. Summer fires dramatically increased the seedling establishment of forbs but had no effect on seedling establishment of grasses.

Seasonality of burning can affect productivity, especially if the fire influences soil drying and moisture levels (Adams and others 1982; Towne and Owensby 1984). Burning in winter or early spring removes the insulation provided by accumulated litter and allows the upper layers of the soil to dry. Burning late in the spring (just after the warm season grasses emerge) removes the thatch, warms the soil, and allows sufficient light to the soil surface; but there is insufficient time for the soil to dry before the grasses begin growing. The effects of the seasonal timing of fire on the tallgrass prairie can be complex depending on time since last fire, latitude, and rainfall. In many cases, timing of rainfall (Benning and Bragg 1993) and microclimate (James 1985) have a greater influence on productivity than season of burning.

Management Considerations—Most studies in the tallgrass prairie show that prescribed fires should be conducted in the fall, early spring, or summer to maximize plant species diversity. However, burning during these times may lead to direct mortality of some animals or to indirect mortality from the removal of protective cover. If weight gain of livestock is the primary goal, the area should be burned in late spring to maximize production of warm season grasses. Additionally, grazing can significantly influence ecosystem responses to fire. Management should strive to preserve heterogeneity through maintenance or simulation of natural disturbance regimes. Where feasible, mowing or grazing (Collins and others 1998) should be considered in conjunction with burning. Steuter (1990) provides an excellent example of the use of a “natural” disturbance regime for grassland conservation and management.

In remnant prairies, heterogeneity within remnants and regionally between remnants is an important management objective. Larger areas of prairie should be managed as patchworks to promote diversity within the area (Coppedge and Shaw 1998; Steinauer and Collins 1996). Ideally, some element of randomness can be incorporated in the fire management program. This can be accomplished by burning some remnants every 1 to 2 years, some every 4 to 5 years, and some areas every 10 years at different times of year. Attempts should be made to burn only part of an area at a given time. This allows refugia for animal species in the unburned thatch. Many insects, which are important pollinators to prairie plants, winter aboveground. If the entire area is burned, whole populations of these species can be destroyed.

The tallgrass prairie is an extremely dynamic ecosystem. Grassland plants have shown genetic changes as a result of management in as little as 60 years (Painter and others 1989). Many species in remnant prairies have become extinct within the last 60 years probably due to fragmentation and certain management practices; more species probably became extinct prior to this (Leach and Givnish 1996). Gibson (1988) observed that even after several years of identical treatment two areas may still have different plant communities, probably a result of past land use. Thus, it is difficult or impossible to answer, “What plant species were originally found in this general area at the time of settlement by Euro-Americans?” Climate variability can have an even stronger influence on the prairie than careful management. Henderson (1992a) stated that “The vegetation of the prairie seemed to change more from one year of severe drought than from 10 years of frequent early spring, late spring, or early fall burning.”

Bay Forests

Vegetation Dynamics—The overstory was historically dominated by one or more of the following: Atlantic white-cedar, bald cypress, pond pine, slash pine, swamp tupelo, and Blackgum. Other overstory species include sweetbay, red bay, loblolly bay, red maple, and sweetgum. The almost impenetrable understory includes lyonias, titi, swamp cyrilla, gallberries, bays, blueberries, huckleberries, wax myrtle, sweetpepperbush, hollies, Virginia willow, various species of greenbrier, and sphagnum moss. The vegetation of all communities is highly correlated to time since the last fire (Christensen and others 1988). Fire is necessary to cycle nutrients, especially on sites with deep organic soils; the absence of fire is more of a disturbance in pocosins than intense fire (Christensen 1981). During drought conditions, the underlying organic soils burn creating substantial smoke problems, often for weeks at a time. The various

plant associations that make up this ecosystem and their response to fire are discussed by Wells (1928), Richardson (1981), Christensen and others (1988), and Richardson and Gibbons (1993).

Management Considerations—Although the original overstory was usually harvested, few bays are currently managed for forest products. In the decades following World War II, management usually consisted of draining, bedding, and planting loblolly or slash pine, or in some cases row crops. On the remaining bays, fire periodicity determines the successional state of the site. If bay forests burn every 2 to 5 decades, they are called shrub bogs (Christensen 1977; Wharton and others 1976), and if burned at least once a decade, herb bogs. If the underlying organic soils are completely consumed, both pocosins and bays will revert to marsh (Richardson and Gibbons 1993). Herb bogs must be burned at least once every decade or they will succeed to shrub bogs (Wharton and others 1976). Where the objective is to maintain herb bogs and their suite of showy herbaceous species, many of special concern, they should be burned on a 1 to 3 year rotation. As succession proceeds, the fire prescription window narrows and becomes less defined. Wind is the major factor determining whether fire will carry through the early successional stages, while drought becomes more important as the flashy herbaceous groundcover is shaded out by the developing shrub layer. Where shrub composition is primarily wax myrtle, gallberry, fetterbush, and other flammable species, such as in the pocosins of North Carolina, these communities remain receptive to wind-driven fires.

Sand Pine

Cone serotiny is weak in the Choctawhatchee variety and strong in the Ocala variety. Both species are thin-barked and easily killed by fire. The Ocala variety recaptures the site with seed from the freshly opened serotinous cones. The Choctawhatchee variety seeds in from adjacent unburned stands. Both varieties are prolific seeders, producing viable seed by age 5 or 6 (Brendemuehl 1990). Two fires in quick succession (less than about 6 years apart) will eradicate this species from a site. Sand pine is somewhat shade-tolerant and rapidly establishes in the direction of the prevailing wind. It often grows in pure, even-aged stands.

Choctawhatchee—This variety is the principal overstory species. Common understory associates include occasional xeric oaks (turkey, bluejack, sand, post) and prickly pear, with a sparse groundcover of wiregrass and bluestems (Brendemuehl 1990).

Young sand pines are sensitive to fire, so when a fire burns through a stand, it usually kills the overstory; however, overstory species composition does not change

because of the copious amount of seed available for regeneration. In fact this variety is often described as a weed species because it tends to invade other vegetation types that are downwind. Because of its thin bark, fire is often used to eradicate it when it seeds into other stands.

Ocala—This variety occurs on nutrient-deficient sands as the dominant overstory species in evenaged stands. Common understory associates include evergreen shrubs such as myrtle, sand live oak, Chapman oak, turkey oak, rusty staggerbush, rosemary, scrub palmetto, and saw palmetto (Christensen 1981, Outcalt 1997). Little groundcover is found on these xeric sites although cup lichen, or deer moss as it is locally known (same species as in the Arctic), is fairly common.

These stands usually burn with an intense, wind-driven fire that generally consumes all live foliage, kills thin-barked trees, and opens cones allowing the stand to regenerate (Cooper 1951, 1965; Cooper and others 1959).

Management Considerations—Industrial plantations of the **Choctawhatchee** variety have been established in inland Florida and about 200 miles north of its natural range on xeric sand-hill sites in west-central Georgia. This variety can withstand light surface fires once it reaches pole size; prescribed fire under mild burning conditions is sometimes used for hazard reduction in plantations. Care must be taken, however, because the boles of even mature trees are quite susceptible to severe surface fires. Because of the lack of understory competition and slow buildup of fuels, the use of fire in the management of this variety is generally not a high priority. Prescribed fire, however, is advocated for regenerating the **Ocala** variety (Cooper 1953, 1973a; Price 1973). A tight prescription and experienced crew are necessary to confine the fire to its intended boundaries and to manage smoke from these stand-replacement fires because of their proximity to urban areas (Custer and Thorsen 1996). See Walker (1967) for a broader discussion of management recommendations for both varieties.

Table Mountain Pine

Vegetation Dynamics—Table Mountain pine is found on xeric, typically south- to west-facing sites (Whittaker 1956) where it is perpetuated by fire, although it will colonize more mesic sites following fire (Williams and Johnson 1990). This species depends upon fire to: (1) melt the wax seal on serotinous cones to release seeds; (2) consume a large portion of the accumulated forest floor to create a receptive seedbed; and (3) reduce competition for sunlight, water, and the pulse of mineralized nutrients important on sterile soils (Zobel 1969). Groeschl and others (1993) stated that fire reduces overall site quality, which results in

a more favorable environment for pine than for xeric-site hardwoods.

After examining fire records from 1960 to 1971 in the southern Appalachians, Barden and Woods (1974) found no occurrence of lightning-caused crown fires, perhaps because fine herbaceous fuels had vanished after decades of fire exclusion. Of 85 lightning fire records, only two fires killed a majority of the overstory and none resulted in more than token pine reproduction (Barden and Woods 1976). Several human-caused crown fires during this period killed most of the overstory and resulted in much better pine recruitment. Sutherland and others (1995) found the same situation upon examining two centuries of evidence in a southwestern Virginia Table Mountain pine community. Most existing stands have resulted from fires associated with logging early in the 20th century (Williams 1998).

Management Considerations—The long-term effects of fire exclusion in the Appalachians are becoming more apparent (Williams 1998). Most stands are now degraded and succeeding toward hardwood dominance (Williams 1998; Williams and Johnson 1992). The increased incidence of bark beetle attacks in these stressed, aging stands is accelerating this successional trend. The Southern Appalachian Mountains Assessment (SAMAB 1996) listed Table Mountain pine as a rare community.

In the 1990s interest increased in restoring Table Mountain pine communities (Waldrop and Brose 1999; Welch and Waldrop, in press). Although other natural events such as ice storms can create canopy gaps, reduced duff depths are the overriding requirement for seedling establishment (Williams and Johnson 1992; Zobel 1969); for this, periodic fire is generally responsible (although see Barden 1977 and Williams 1998). Questions regarding the necessity of crown fires are still unresolved (Waldrop and Brose 1999; Whittaker 1956; Zobel 1969) but may be answered by future research.

Spruce-Fir

Spruce-fir forests are a related variant of the extensive boreal forest biome described in chapter 3. Historically, the spruce-fir type was virtually fireproof (Harmon and others 1983; Korstian 1937), but logging followed by fire has devastated this forest type in the Southern Appalachians (Korstian 1937). In many cases, the deep duff layers have been consumed down to bare rock, and species composition has shifted to yellow birch, pin cherry, and mountain ash. According to

Minckler (1944), rehabilitation of these sites will take 500 to 1,000 years.

Mature spruce may initially survive low-intensity fires, but Stickel and Marco (1936) found that over half the survivors had been attacked by fungi, insects, or both within 3 years postburn. Thus underburning does not appear to be an appropriate practice in management of this forest type. See Walker (1967) for more discussion of management recommendations.

Atlantic White-Cedar

Vegetation Dynamics—Once trees reach pole size, copious amounts of seed are produced (about 500,000 per pound) from several thousand cones per tree. The seed is released every fall and stored in the forest floor where it remains viable for about 3 years. Stands tend to be exceedingly dense. Lower branches die at an early age but persist for several decades before being sloughed off. Under normal (wet) conditions, crown fires destroy the aboveground vegetation. As droughts get progressively worse, more of the forest floor and stored seed are consumed. Two fires in close succession, before the seed bank is replenished, will produce herb bog, shrub bog, or bay forest depending upon the future fire return interval.

Reestablishment after fire depends upon fire severity and age of the stand. When the water table is high and fires just skim off the top of the forest floor, the replacement stand can be Atlantic white-cedar, pond pine, or sprouting hardwood trees and shrubs. Succession depends upon the amount of stored cedar seed, preburn species composition, and the composition of unburned adjacent stands. Fires during severe drought, which consume much of the organic soil, result in open water and a dense cover of leatherleaf, hardwoods capable of sprouting, and cedar, depending on the factors just mentioned and postfire precipitation (Little 1959).

Generally, dense stands of Atlantic white-cedar are formed after fire when the water table is neither much above nor below the top of the peat. A high water table allows sprouting hardwoods to gain a competitive advantage before cedar seeds germinate. A low water table allows most of the cedar seed to be consumed. In both cases, regeneration may be insufficient to produce a monotypic cedar canopy.

Management Considerations—Current fire management of Atlantic white-cedar stands is to exclude all fire until the stands are harvested. Then fire can be used to dispose of logging debris and prepare the site for the next crop. See Walker (1967) for more discussion of management recommendations.

Stephen F. Arno

Chapter 5: Fire in Western Forest Ecosystems

Understory Fire Regimes _____

Major Vegetation Types

Major forest types that are characterized by nonlethal understory fire regimes include those where ponderosa pine or Jeffrey pine has been a major component either as a fire-maintained seral type or as the self-perpetuating climax (table 5-1). This includes extensive areas throughout the Western United States from northern Mexico to southern British Columbia, Canada (Little 1971). Also, sizeable areas of open woodlands dominated by Oregon white oak, California black oak, blue oak, or Digger pine were characterized by frequent understory fires largely due to deliberate burning by Native Americans (Boyd 1986; Lewis 1973). These occurred in relatively dry areas west of the Cascades and Sierra Nevada from the southwest corner of British Columbia to southern California. Recent studies suggest that large areas of the redwood forest in coastal northern California were characterized by frequent understory fires resulting from burning by Native Americans (Brown and Swetnam 1994; Duncan 1992; Finney and Martin 1989; Greenlee and Langenheim 1990).

Additionally, portions of other forest types may also have had understory fire regimes. For example, some areas of interior Douglas-fir near the drought-caused lower timberline in the higher valleys of the Rocky Mountains may have been maintained in open condition in understory fire regimes (Arno and Gruell 1983; Arno and Hammerly 1984). Nevertheless, most of this type is best represented by the mixed regime.

Fire Regime Characteristics

Fires were frequent, with mean intervals between 5 and 30 years in most areas (Kilgore 1987; Martin 1982) in the ponderosa pine type and at similar intervals in the redwood type; fires occurred even more frequently in some of the oak-prairie communities. At one extreme, fire intervals averaged 1 to 2 years in an area of northern Arizona and no more than 10 years throughout the Southwestern ponderosa pine type due to abundant lightning activity (Dieterich 1980). Conversely, near the cold limits of the ponderosa pine type in western Montana, mean fire intervals averaged between 25 and 50 years (Arno and others 1995b). Relatively short mean intervals occurred where many ignitions were made by Native Americans, while longer

Table 5-1—Occurrence and frequency of presettlement fire regime types by Forest and Range Environmental Study (FRES) ecosystems, Kuchler potential natural vegetation classes (1975 map codes), and Society of American Foresters (SAF) cover types. Occurrence is an approximation of the proportion of a vegetation class represented by a fire regime type. Frequency is shown as fire interval classes defined by Hardy and others (1998) followed by a range in fire intervals where data are sufficient. The range is based on study data with extreme values disregarded. The vegetation classifications are aligned to show equivalents; however, some corresponding Kuchler and SAF types may not be shown.

intervals occurred on similar forest sites that were more remote from aboriginal occupation. For example, in a western Montana study the mean fire interval from 10 heavily used areas was 9 years while the mean interval from 10 remote areas on similar sites was 18 years (Barrett and Arno 1982).

In the Southwestern ponderosa pine type, major fire seasons occur after snow melt (April and May) and in mid-summer just before the monsoon rains begin, and a secondary season exists in the fall. In most other areas the main lightning fire season is summer; whereas Indian burning apparently occurred to some extent in spring, summer, and fall (Barrett and Arno 1982; Gruell 1985a, 1985b). Low-intensity surface fires were characteristic and may have been quite large where dry forests and adjacent grasslands were extensive—for example, on the gentle topography of high plateaus in northern Arizona and New Mexico. In contrast, in rugged mountainous topography, the understory fire regime was often confined to small areas of dry sites on south-facing slopes (Arno 1980). The adjacent moist sites supported other, denser forest types, which burned less often and in mixed or stand-replacement fire regimes. When stand-replacement fires burned the adjacent moist types in 1889 and 1910 in the Northern Rocky Mountains, the dry forest types still burned primarily in a nonlethal manner. See chapter 6 for additional information about the Southwestern ponderosa pine type.

Fuels

During periods of high fire frequency, fuels were primarily herbaceous material and forest floor litter. After fire suppression became effective, forest floor duff and live fuels such as shrubs and conifer regeneration accumulated. Measurements in recent decades (Brown 1970; Brown and Bevins 1986; Sackett 1979) show that litter typically ranges from 0.6 to 1.4 tons/acre (1.3 to 3.1 t/ha) and the entire forest floor of litter and duff averages about 12 tons/acre (27 t/ha) in both Arizona and Northern Rocky Mountain areas. Forest floor quantities as high as 40 tons/acre (90 t/ha) have been measured (Harrington 1987b). During periods of frequent fire, forest floor quantities would typically range from 1 to 4 tons/acre (2.2 to 9.0 t/ha). Herbaceous fuels range from practically none in dense stands to as much as 0.5 tons/acre (1.1 t/ha) in open stands on productive sites. In the Black Hills of South Dakota, herbaceous fuel quantities in open stands of ponderosa pine averaged 440 lb/acre (490 kg/ha), which was six times greater than in closed stands (Uresk and Severson 1989). Herbaceous fuel quantities are typically about 400 lb/acre (448 kg/ha).

Frequent low-intensity surface fires perpetuated open stands of trees whose lower branches were killed by fire. With fire suppression, accumulated fuels

support higher intensity fire including torching and crowning behavior and longer periods of burnout. The increased burn severity results in greater mortality to plants and soil organisms. Managers can easily overlook the significance of forest floor fuels; the upper layer (litter) and part of the middle (fermentation) layer provide the highly combustible surface fuel for flaming combustion and extreme fire behavior during severe fire weather. The lower part of the fermentation layer and the humus layer make up the ground fuel that generally burns as glowing combustion. A substantial amount of forest floor material can remain after an area is initially burned (Sackett and Haase 1996).

Postfire Plant Communities

Ponderosa Pine/Jeffrey Pine and Ponderosa Pine-Mixed Conifer

Pre-1900 Succession—These semiarid forest types are widespread in the inland portions of western North America. They include pure pine climax types, which are abundant in plateau areas of northern Arizona and New Mexico, central Oregon, and eastern Washington. They also encompass many sites in the inland mountains where pines are seral to more shade-tolerant conifers—interior Douglas-fir, white fir, grand fir, or incense-cedar. Prior to 1900 these pine communities experienced frequent fires as a result of highly combustible leaf litter, an abundance of cured herbaceous vegetation, and a long season of favorable burning weather. Stands had an open, parklike appearance, dominated by large old, fire-resistant trees. Shrubs, understory trees, and downed logs were sparse, as testified to by dozens of historical photographs and narrative accounts (Cooper 1960; Leiberg 1899; Wickman 1992). Travelers often rode horseback or pulled wagons for miles through these forests without the need of cutting trails.

Undergrowth was primarily of fire-resistant grasses and forbs that resprouted after each burn. Shrubs were suppressed by the frequent burning coupled with overstory competition (Gruell and others 1982). In most stands, duff depth probably averaged only about half an inch (Keane and others 1990a). The majority of overstory trees survived each fire, while many of the understory trees were killed. The most fire-resistant species—ponderosa pine, Jeffrey pine, and western larch—were favored. In the large areas of this type where ponderosa pine is seral, it maintained dominance only because of the frequent fires.

In much of the pure ponderosa pine type and in the seral pine type on dry sites, pine regeneration occurred whenever overstory trees died, thereby creating small openings. These open microsites allowed a few seedlings to grow fast enough to gain resistance to survive the next fire (Cooper 1960; White 1985). Thus

stands tended to be uneven-aged and often contained some 400 to 600 year old trees (Arno and others 1995b, 1997). Trees were often distributed in small even-aged clumps. When small patches of overstory were killed by fire or bark beetles, subsequent fires consumed these fuel concentrations, locally reducing grass competition and creating mineral soil seedbeds. This favored establishment of ponderosa pine seedlings, allowing a new age class to develop in a micromosaic pattern within a stand (Cooper 1960). These effects helped create an uneven-age stand structure composed of small, relatively even-aged groups (Cooper 1960; Arno and others 1995b).

Mixed-severity fire regimes were characteristic on some of the relatively moist sites and on steep slopes throughout the ponderosa pine type. Variable and mixed regimes were evidently widespread in ponderosa pine communities in the Front Range in Colorado and in the Black Hills of South Dakota and Wyoming, and stand-replacement regimes occurred in some situations in the Black Hills. These are described under the section "Mixed Fire Regimes," later in this chapter.

Post-1900 Succession—Important changes have occurred in these forests since 1900 due to interruption of frequent burning. Nonlethal fire has decreased while lethal fire has increased (fig. 5-1). Reduced fire began in the late 1800s as a result of (1) relocation of Native Americans and disruption of their traditional burning practices; (2) fuel removal by heavy and extensive livestock grazing; (3) disruption of fuel continuity on the landscape due to irrigation, cultivation, and development; and (4) adoption of "fire exclusion" as a management policy. The general result has been development of dense conifer understories, commonly adding 200 to 2,000 small trees per acre beneath old growth stands or thickets of 2,000 to 10,000 small trees per acre where the overstory was removed. Densely overstocked conditions have resulted in slow growth and poor vigor of most trees in a large proportion of the ponderosa pine type where adequate thinning treatments have not been applied. Stand stagnation is accompanied by a sparse representation of nonflowering herbs and shrubs, which reflects a loss of natural biodiversity and of forage for wildlife (Arno and others 1995a). Growth stagnation renders even the dominant trees highly vulnerable to mortality in epidemics of bark beetles, defoliating insects, diseases such as dwarf mistletoe, and various root rots (Biondi 1996; Byler and Zimmer-Grove 1991; Cochran and Barrett 1998). For example, in the 1980s about a million acres of ponderosa pine-fir forests in the Blue Mountains of eastern Oregon suffered heavy mortality from the above agents as a result of overstocking and growth stagnation related to fire exclusion (Mutch and others 1993).

Figure 5-1—Change in fire severity between historic (pre-1900) and current conditions for Forest Service and Bureau of Land Management administered forested potential vegetation groups in the Interior Columbia Basin and portions of the Klamath and Great Basins (Quigley and others 1996).

In many stands, duff mounds 6 to 24 inches deep have accumulated under old growth trees, and burning these mounds may girdle and kill the trees (fig. 5-2). Stands of small, slow-growing pines have also colonized former grasslands (Gruell 1983). Overstory trees have been removed in more than a century of logging, primarily partial cutting, and this has aided development of thickets of small trees. On sites where ponderosa pine is seral, there has been a compositional shift to the shade-tolerant species. These successional changes have resulted in a buildup of understory or ladder fuels that now allow wildfires to burn as stand-replacing crown fires.

A combination of heavy forest floor fuels and dense sapling thickets acting as ladder fuels, coupled with the normally dry climate and frequent lightning- and human-caused ignitions, has resulted in a dramatic increase of severe wildfires in the ponderosa pine type in recent decades (Arno 1996; Williams 1995). For example, approximately 1 million acres (405,000 ha), largely in this type, burned in severe wildfires in central Idaho between 1986 and 1996 (Barbouletos and others 1998).

Management Considerations—Fires of the past were important to the evolution of ponderosa and Jeffrey pine forests (Keane and others 1990a; Mutch 1970; Weaver 1967). Today, prescribed fire and wildland fire are the obvious and most feasible substitutes for filling the ecological role of historic fires in restoring these wildland ecosystems (fig. 5-3). Many alternatives exist for employing prescribed fire and fuels management treatments to improve forest health and reduce excessive ladder fuels in ponderosa pine and pine-mixed conifer types (Arno 1988). Different prescriptions can be chosen to enhance critical resources or values (Fiedler and others 1996), such as maintenance of old growth in a natural area, encouraging

Figure 5-2—A prescribed burn during October in central Idaho removed duff as thick as the distance between the hands, in this case with little damage to large ponderosa pine trees.

Figure 5-3—Prescribed fire during May is being used to reduce fuel loadings after a retention shelterwood harvest in a ponderosa pine/Douglas-fir forest.

browse and cover on a big game winter range, maintaining forest structure favored by neotropical migrant bird species, northern goshawk, flammulated owl, and other species of concern; protecting homes and watersheds from severe wildfire while maintaining visual screening; or providing a continuous supply of forest products without disruption of esthetics. However, most long-term management goals for wildlands in these forest types can be enhanced by some form of prescribed fire and fuels management.

Many contemporary stands have such an altered stand structure and composition, including a buildup of understory fuels, that it is difficult to restore forest health with prescribed fire alone. Silvicultural cutting and pile-burning or removal of excess small trees may be necessary to allow successful application of prescribed fire and to return to more open structures dominated by vigorous trees of seral species (Arno and others 1995a). Failed attempts to restore more natural stand conditions with prescribed burning alone may result from inappropriate use of fire as a selective thinning tool in dense fire-excluded stands, or from burning too little or too much of the accumulated forest floor fuels. A better approach to the latter problem may be to apply two or even three burns to incrementally reduce loadings (Harrington and Sackett 1990). Once a semblance of the desired stand and fuel conditions have been established, stands can thereafter be maintained more routinely with periodic burning or a combination of cutting and fire treatments. Prescribed fire can be used in wildernesses and natural areas to maintain natural processes.

The advantages of using fire and improvement cuttings to restore and maintain seral, fire-resistant species include: (1) resistance to insect and disease epidemics and severe wildfire; (2) providing continual forest cover for esthetics and wildlife habitat; (3) frequent harvests for timber products; (4) stimulation of forage species; and (5) moderate site disturbances that allow for tree regeneration (Mutch and others 1993). Frequent prescribed fires will not produce heavy screening or hiding cover, which is not sustainable over large areas in these forests. But such fires can help maintain moderate cover and screening indefinitely (Martin and others 1988). Management of a large proportion of the forest in open conditions can help ensure protection of strategically located patches of heavier cover (Camp and others 1996). The frequent disturbance cycles can also produce and maintain large old trees characteristic of pre-1900 forests and of high value for wildlife habitat, esthetics, and selective harvesting for lumber. In other words, the management approach of using a modified selection system and periodic burning can be used to maintain remnant old growth stands and to create future old growth (Fiedler 1996; Fiedler and Cully 1995).

Prescribed fire and wildland fire must be introduced cautiously in stands where leave trees have poor vigor or where tree roots are located in a deep duff layer (Harrington and Sackett 1992). Burning thick forest floor fuel layers can mortally injure roots and boles of old pines that in past centuries survived many fires (Sackett and Haase 1996). Exceptionally poor tree vigor is reflected by growth stagnation over two or more decades in the dominant trees in both second growth and old growth stands. This widespread stand stagnation has resulted from basal area stocking levels often two or more times those of historic conditions (Arno and others 1995b; Biondi 1996; Cochran and Barrett 1998; Habeck 1994). Fire can be highly stressful to trees that are suffering from growth stagnation, and may, for instance, allow bark beetles to inflict major damage to the weakened trees. If vigor of desired leave trees is poor, it may be wise to thin mechanically and allow the leave trees to recover or release somewhat before applying fire, in perhaps 2 years (Fiedler and others 1996).

Options for alleviating the condition of poor vigor or deep duff are not ideal. Managers can simply accept a 20 to 50 percent loss of old growth in a single fuel-reduction burn as being a cost of decades of fuel buildup. Most old growth stands are now more heavily stocked than in pre-1900 times, and some of the trees would probably have been killed by natural fires had suppression not intervened. Alternatively, fuels could be manually removed or raked away and dispersed from around the boles of old growth trees. The use of a burn prescription that reliably removes a portion of the fuel mound around a big tree has not been found. If glowing combustion is able to establish in the deeper mounds, it can continue even with high moisture content of that material and result in total consumption and prolonged heat release.

Improvement cutting, thinning, and understory cutting with whole-tree removal or pile burning may be necessary to achieve open stocking levels that will sustain vigorous tree growth and to reduce ladder fuels (Fiedler and others 1996) (fig. 5-4). Harvesting and thinning should be designed to retain the most vigorous trees. If stems are tall and slender, as in dense second growth stands, it may be necessary to leave clumps of three to five trees for mutual protection against breakage by wet snow and windstorms. The restoration cutting process may require thinning in two to three steps over 15 to 20 years. Spot planting of the desired seral tree species in open burned microsites can be used when shade-tolerant species have taken over (Fiedler and others 1996).

Prescribed fire can be used in a variety of seasons to meet management objectives (Harrington 1991; Kalabokidis and Wakimoto 1992; Kauffman and Martin 1990; Kilgore and Curtis 1987; Martin and Dell

Figure 5-4—(A) An unwanted ponderosa pine-fir stand that resulted from partial cutting of large pines followed by development of fir thickets. (B) Similar stand after the first restoration treatment consisting of thinning to favor remaining pines and jackpot burning.

1978; Weatherspoon 1990). This includes burning in late winter following snowmelt, when understory Douglas-fir or true firs may burn readily and are easily killed because of low foliar moisture content; spring; cloudy-humid days in summer; or autumn. Trees are less susceptible to fire damage when entering dormancy in late summer and fall. Potential for fire damage can be reduced by thinning and whole-tree removal, burning when slash is still green, successive burns starting with damp fuels, and raking duff mounds away from boles of old growth trees. Fire intensity can be reduced by burning at dawn, late evening, or at night. Conversely, to enhance burning in stands where surface fuels are inadequate, such as in fir thickets, thinning can be used to create sufficient loadings of cured slash. Alternatively, waiting for grass fuels to cure in the fall may be effective. If enclaves of dense growth are desired, such as for wildlife habitat, these can be protected from wildfire if buffered within a matrix of treated stands that have light fuel loadings.

During the past decade tens of thousands of acres of the ponderosa pine type have been treated with prescribed fire in central Oregon, northwestern Montana, and parts of Arizona and New Mexico (Kilgore and Curtis 1987; Losensky 1989; Simmerman and Fischer 1990). If these applications can be greatly expanded they could correct some of the severe forest health and wildfire problems that exist in the Inland West (Everett 1994; McLean 1992; Mutch and others 1993).

Redwood

Pre-1940 Succession—Forests where redwood was the most abundant tree covered about 1 million acres in a narrow strip along the coastal fog belt from the extreme southwestern corner of Oregon to Monterey County, California (Roy 1980). It has long been recognized that relatively frequent understory fires were historically a common feature of the redwood forest and that fires seldom killed many of the large redwood trees (Fritz 1931). Redwood is even more fire resistant than coast Douglas-fir, its primary associate, and unlike most conifers in this region, redwood sprouts vigorously from dormant buds when the crown is heavily scorched. Pacific madrone and tanoak, the most abundant hardwoods in the redwood type, are fire susceptible. They resprout when top-killed by fire, but burning probably taxed them physiologically when they were growing beneath an overstory.

Recent advances in dating fire scars on redwood stumps have shown that presettlement (pre-1850) fire intervals averaged between about 5 and 25 years, shorter than previously estimated (Brown and Swetnam 1994; Finney and Martin 1989, 1992). The pattern of frequent fires on fire-scarred tree stumps was traced back to about 1300 A.D. in one study area (Finney and Martin 1989) and to about 800 A.D. in

another (Fritz 1931). There is a convergence of evidence from historical journals and archeological and anthropological discoveries that Indian burning was primarily responsible for the frequent fires prior to the mid-1800s (Duncan 1992; Greenlee and Langenheim 1990; Lewis 1973; Stuart 1987). Coincidentally, the redwood forest is located close to interior coastal valleys where detailed journal accounts of Indian burning have been assembled (Boyd 1986, 1999). In the pre-settlement period, before logging occurred, the frequent fires probably kept understories open and reduced forest floor fuels. Overstories of the tall trees with branch-free lower boles were relatively dense because of high site productivity and redwood's fire resistance.

During the settlement period, in the later 1800s and early 1900s, Anglo-Americans conducted logging that created large quantities of slash. These inhabitants continued a pattern of frequent burning in conjunction with logging and for grazing or other purposes. They also allowed accidental fires to spread.

Post-1940 Succession—Starting in the 1930s and 1940s, land use patterns changed with the implementation of the California Forest Practices Act and with more vigorous fire suppression (Greenlee and Langenheim 1990; Stuart 1987). The number of escaped fires from agricultural or logging activities was reduced greatly; but the effects of this reduction of fires have received little evaluation. It is generally assumed that the long-lived, shade-tolerant redwoods will continue to dominate regardless of removal of underburning. Successional relationships in redwood forest communities (Zinke 1977) suggest that with suppression of underburning, shade-tolerant shrubs, understory hardwoods, and western hemlock will increase as will forest fuels in general. In the extensive parks and preserves where redwood forests are protected from logging, continued exclusion of fire will probably allow fuels to accumulate to levels that support higher intensity wildfires, which can escape suppression. Thus, the removal of underburning may ultimately result in a mixed fire regime where wildfires kill significant portions of the overstory and may induce soil damage on the steep slopes associated with a large portion of the redwood type (Agee 1993; Atzet and Wheeler 1982). Additionally, removal of underburning will probably reduce the abundance of early seral species (including chaparral species) and will allow trees to colonize the small openings and prairies associated with the redwood forest belt (Finney and Martin 1992; Greenlee and Langenheim 1990; Zinke 1977).

Oregon Oak Woodlands

Pre-1850 Succession—Open woodlands dominated by Oregon white oak once occupied the driest climatic areas throughout the Puget Sound-Willamette Valley

lowlands and southward in dry valleys behind the coastal mountains to the California border. (Farther south this woodland expands to cover large areas of dry hilly terrain and it is dominated by several species of oak in addition to other hardwood trees; those communities are described under “Western Oaks” in chapter 6.) Oregon white oak dominated in open woodlands and savannas associated with valley grasslands, and isolated small prairies that were surrounded by the extensive coast Douglas-fir forest. Oak woodlands also were associated with droughty sites such as bedrock with shallow soils on the southeast coast of Vancouver Island and in the San Juan archipelago, in the rain shadow of the Olympic Mountains.

Ample evidence from journal accounts and archeological sources shows the extensive oak woodlands of the Willamette and other major valleys persisted as a “fire climax” maintained by frequent aboriginal burning (Agee 1993; Boyd 1986, 1999; Habeck 1961). Prior to the influx of Euro-American settlers in the mid-1840s, the Kalapuyan Indians and other tribes typically set fire to large areas of the Oregon oak woodlands to aid hunting, food plant harvest, and for other purposes (Boyd 1986). Firing was commonly done in September, and many areas were burned at short intervals, perhaps annually in some areas. Similar patterns of frequent burning to maintain valley grasslands, isolated prairies, and open oak woodlands are described from northwestern Washington southward to central California (Lewis 1973; Boyd 1986, 1999), but these practices are well documented only in the Willamette Valley of northwestern Oregon.

Most of these fires must have been characterized by short duration flaming as they quickly consumed grass and litter that had accumulated since the previous burn. The thick-barked oaks survived, but regeneration of all shrubs and trees would have been heavily thinned by frequent burning. Grass flourished. The effect of frequent burning on oak regeneration from sprouts and seedlings is not known, but this species was more successful in establishment than Douglas-fir or other competitors under a regime of frequent burning. Results of experimental burning suggest that heavily burned microsites are favorable for oak seedling establishment (Agee 1993). Also, about half of the 1 to 9 year old seedlings burned in a prescribed fire resprouted and were alive 3 years later.

Post-1850 Succession and Management Considerations—In former oak savannas, fire exclusion has led to an increased density of shrubs and oaks, transforming them into woodlands (Agee 1993). In former oak woodlands, shrubs, Douglas-fir, and other tree species are replacing oaks. Livestock grazing and fire exclusion have been major factors in the successional change that has occurred in Oregon oak woodlands since Euro-American settlement. Logging,

clearing, and firewood harvest also have changed many woodlands. Additionally, large areas of oak woodlands have been displaced by agricultural, commercial, industrial, and residential development.

Today, 150 years after Euro-American settlement began, only a general idea of presettlement conditions can be hypothesized for most stands. Much of the remaining undeveloped area in this type will be replaced successional by the year 2010 unless prescribed fire and other restoration treatments are conducted (Agee 1993). To complicate restoration of oak communities, a variety of introduced herbaceous plants and the shrub Scotch broom are now established. Introduced plants can increase as a result of some treatments. Nevertheless, some strategies of burning carefully coordinated with cutting, seeding of native plants, and other treatments hold some promise (Agee 1993; Sugihara and Reed 1987). Restoration of structural characteristics of the oak communities is an attainable goal (see Agee 1993).

Mixed Fire Regimes

Major Vegetation Types

Major forest types include coast Douglas-fir, redwood, California red fir, interior Douglas-fir, western larch, lodgepole pine, whitebark pine, and ponderosa pine types east of the continental divide in Montana, South Dakota, Wyoming, and Colorado. (There is evidence that a mixed regime may have been important for perpetuation of giant sequoia groves in the Sierra Nevada; Stephenson and others 1991; Swetnam 1993.) These forests are widespread in the upper Great Plains, the mountains of the Western United States, and in the northwest coastal regions, extending into southern British Columbia (fig. 1-2). In large portions of their distributions, some of these forest types are also characterized by stand-replacement fire regimes in large portions of their distributions, evidently as a result of differences in climate or topography. An example of this contrast is the larch-lodgepole pine forest in Glacier National Park, Montana, where the northern portion was under a mixed fire regime while the southern portion had a stand-replacement fire regime (Barrett and others 1991). A similar contrast is provided by lodgepole pine types in southwestern Alberta as described by Tande (1979) and Hawkes (1980).

Fire Regime Characteristics

Fires were variable in frequency and severity, and perhaps because these situations are difficult to characterize in simple terms, they have been largely overlooked in previous fire regime classifications (Brown 1995). Mean fire intervals were generally longer than

those of understory fire regimes and shorter than those in stand-replacement fire regimes. However, some individual fire intervals were short (<30 years), while the maximum intervals could be quite long (>100 years). Our mixed category covers the spectrum of fire regimes between nonlethal regimes and those where stand-replacement fires were typical.

As described in chapter 1, mixed fire regimes may consist of a combination of understory and stand-replacement fires. Examples are the seral ponderosa pine-western larch forests in western Montana that burned in replacement fires at long intervals (150 to 400+ years) with nonlethal underburns at short intervals (20 to 30 year averages) in between (Arno and others 1995b, 1997).

Mixed severity fire regimes may also be characterized by fires that killed a large proportion of fire-susceptible species in the overstory (such as western hemlock, subalpine fir), but spared many of the fire-resistant trees (such as redwood, Douglas-fir, larch, ponderosa pine). These fires tended to burn in a fine-grained pattern of different severities, including patches where most of the moderately susceptible trees (such as California red fir, white fir, lodgepole pine) survived. Any given location within a mixed fire regime could experience some stand-replacement fires and some nonlethal fires along with a number of fires that burned at mixed severities.

Evidence of mixed severity fire in ponderosa pine is suggested in two landscape photocomparisons of central Montana from the 1880s to 1980 (Gruell 1983, plates 32 and 43). Relatively long fire intervals and mixed burning also occurred in ponderosa pine in the Colorado Front Range (Laven and others 1980) and in the Black Hills of South Dakota (Brown and Sieg 1996; Shinneman and Baker 1997). The mixed fire regime is reported to have been common in mixed-conifer forests of northern Idaho (Zack and Morgan 1994; Smith and Fischer 1997) and western Montana (Arno 1980).

Pre-1900 fires often covered large areas. The uneven burning pattern in mixed fire regimes was probably enhanced by mosaic patterns of stand structure and fuels resulting from previous mixed burning. Thus, past burn mosaics tended to increase the probability that subsequent fires would also burn in a mixed pattern. Complex mountainous topography also contributed to variable fuels and burning conditions, which favored nonuniform fire behavior.

Fuels

During the presettlement period fuels were probably quite variable spatially and temporally. At a given time, some segments of the vegetative mosaic would be patches of postfire regeneration that had arisen where the last fire killed much of the overstory. Fuel loadings in these patches might increase

dramatically as dead trees and limbs fell into a developing patch of saplings. If these regenerated patches burned again, the resulting "double burn" might be an area cleared of most living and dead fuel and thereafter more likely to support nonlethal underburning in the next fire. In the presettlement period a given fire could burn day and night for 2 to 3 months under a great variety of weather conditions in a hodgepodge of different vegetation and fuel structures. Reburning might occur later in the same fire event. This could result in an intricate pattern of different fire effects on the landscape. Such complex burning patterns are difficult to imagine in modern stands where 60 to 100 years of fire exclusion have allowed most of the landscape mosaic to age and advance successional. Patches of late-successional forests with accumulations of dead and living fuels have coalesced, increasing the likelihood of fires of unusual size and severity (Barrett and others 1991).

The ranges in fuel loadings observed in vegetation types characterized by mixed and stand-replacement fire regimes exhibit considerable overlap. Fuel loadings vary widely within broad vegetation classes due to stand history and site productivity. Dead woody fuels accumulate on the ground often in a haphazard manner due to irregular occurrence of natural mortality factors such as fire, insects, disease, tree suppression, and wind and snow damage. However, the greatest fuel loadings tend to occur on the most productive sites, which are predominately stand-replacement fire regimes. For example, in the Northern Rocky Mountains downed woody fuel loadings ranged from an average of about 10 tons/acre (22 t/ha) on low productivity (30 cu ft/acre/yr) sites to about 30 tons/acre (67 t/ha) on high productivity (90 cu ft/acre/yr) sites (Brown and See 1981).

Average fuel loadings determined from extensive forest surveys in the Northern Rocky Mountain National Forests (Brown and Bevins 1986; Brown and See 1981) indicate that quantities of duff and downed woody material differ between mixed and stand-replacement fire regimes (table 5-2). For example, total woody fuel loadings for the spruce-fir and cedar-hemlock types, which are stand-replacement regimes, averaged about 30 tons/acre. It averaged about 17 tons/acre in Douglas-fir and lodgepole pine types, which are characterized by mixed and stand-replacement regimes. Variability within stands and cover types was considerable. Fuel loading distributions for forest floor and all classes of downed woody material were highly skewed, with long right-handed tails. The ratios of medians-to-means averaged close to 0.6 (Brown and Bevins 1986). These statistics indicated that fuels were not uniformly distributed but concentrated in scattered patches.

Downed woody fuels greater than a 1 inch diameter are considered coarse woody debris, which has

Table 5-2—Average loadings of forest floor and downed woody fuel by diameter class for randomly located sample points in Northern Rocky Mountain forest types: Douglas-fir (DF), Lodgepole Pine (LP), Larch/grand fir (L/GF), Spruce/fir (S/F), and Cedar/hemlock (C/H).

Fuel	USDA Forest Service forest survey cover types				
	DF	LP	L/GF	S/F	C/H
	----- tons/acre -----				
Litter	0.56	0.35	0.66	0.52	0.85
Duff	13.0	16.0	21.8	25.4	25.4
Woody					
0 to ¼ inch	.18	.22	.22	.12	.30
¼ to 1 inch	1.0	1.0	1.3	1.0	1.3
1 to 3 inches	1.8	2.1	2.3	1.9	2.7
3+ inches	12.9	14.4	17.7	23.8	29.4
Total woody	15.9	17.7	21.5	26.8	33.7

important implications for managing biodiversity and nutrient potentials. Based on a survey of coarse woody debris knowledge (Harmon and others 1986) quantities of downed woody material are considerably higher in Cascade Mountains and coastal forests than in the Northern Rocky Mountains. Loadings of coarse woody debris ranged from 60 to 300 tons/acre (130 to 670 t/ha) in Sitka spruce and western hemlock of coastal British Columbia and from 60 to 240 tons/acre (130 to 540 t/ha) in the Douglas-fir type of the Cascade Mountains.

Postfire Plant Communities

Coast Douglas-fir and Douglas-fir/Hardwoods

Pre-1900 Succession—These humid maritime forests are extensive at low and middle elevations west of the crest of the Cascades and British Columbia Coast Range from northern California to southern British Columbia. Fire history studies (see Agee 1993) indicate that mixed fire regimes were common in the Douglas-fir type south from west-central Oregon; drier areas of the Douglas-fir type farther north; and in the Douglas-fir/hardwood types of northwestern California and southwestern Oregon (Wills and Stuart 1994) (fig. 5-5). Conversely, the cooler, wetter, more northerly portions of the coast Douglas-fir type tended to be associated with stand-replacing fire regimes. Mixed fire regimes were probably also associated with some areas of the redwood type, perhaps on steep terrain and in areas relatively remote from Native American use.

Mixed fire regimes favored development of stands dominated by large old, fire-resistant trees, such as coast Douglas-fir—and, where present, redwood. These regimes were characterized by patchy nonuniform burning (Morrison and Swanson 1990; Teensma 1987; Wills and Stuart 1994). Overall, most of the

fire-susceptible trees (notably western hemlock) were killed while many of the resistant trees survived. Occasional nonlethal understory fires and stand-replacement fires also occurred. Effects of burning included removing understory conifers and ladder fuels, preventing successional replacement by shade-tolerant trees, and creating openings of all sizes that allowed regeneration of seral undergrowth (including berry-producing shrubs), hardwood trees (such as red alder, bigleaf maple, bitter cherry), Douglas-fir and a few other seral conifers (such as western white pine and shore pine).

In northwestern California and southwestern Oregon, dry Douglas-fir/hardwood types burned rather frequently and supported a variety of seral shrubs, including *Ceanothus* spp. as well as hardwood trees that typically resprout after fire—including tan oak, madrone, canyon live oak, and chinquapin (Agee 1993; Husari and Hawk 1993; Wills and Stuart 1994). A remarkable feature of the mixed fire regimes in dry sites was the prevalence of large (>6 feet in diameter), old Douglas-fir that had survived numerous fires. Although forests associated with this fire regime type are extensive and important for a variety of ecological values, little is known about landscape patterns and successional patterns associated with the presettlement fires. The existence of this mixed fire regime as a widespread type was documented only recently (Agee 1993; Means 1980; Morrison and Swanson 1990).

Post-1900 Succession—Better knowledge of the ecological role and importance of fire in these mixed fire regimes is needed (Kauffman 1990). Although major ecological changes in these forests due to clearcutting and short-rotation forest management have been recognized, other significant changes have also occurred as a result of interruption of the mixed fire regime (Agee 1990). Effects of fire exclusion are

Figure 5-5—Coastal Douglas-fir in a dry area of northwestern Washington, with scars from two different historic fires.

conspicuous in dry site coastal Douglas-fir communities which burned rather frequently, for example, those in southwestern Oregon (Agee 1991; Means 1982) and in the Puget Sound lowlands (Agee and Dunwiddie 1984; Boyd 1986). Such effects include loss of early seral shrub species, advanced successional development, increased stand density, and increased mortality. In older logged areas it is common to find dense second growth Douglas-fir and hemlock that are stagnating and succumbing to root rot, whereas the original stands consisted of large Douglas-fir in moderately open stands that had survived for several centuries in the presence of repeated fires.

Management Considerations—These forest types have high value for recreation, esthetics, endangered species habitat, and timber production. It is generally recognized that fire had an important role in creating these forests. A century ago Gifford Pinchot, Forester for the U.S. Department of Agriculture, argued for research into the ecological role of fire in these forests, but his call went largely unheeded (Pinchot 1899). Most fire research in these vegetation types has been related to burning of clearcuts (Kauffman 1990), and provides knowledge that is of limited value for modern ecological application. Other ecological aspects of these forests have been studied in detail at the H. J. Andrews Experimental Forest in west-central Oregon (Franklin

and Others 1981; Teensma 1987) and in some redwood ecosystems (Zinke 1977). Major forest preservation efforts have focused on these forests, but ironically have generally accepted the continued exclusion of fire as consistent with maintenance of ecological values.

California Red Fir and Sierra/Cascade Lodgepole Pine

Pre-1900 Succession—These are high elevation forests characteristic of the southern Cascades, Klamath Mountains (in northwestern California), and the Sierra Nevada. Fire history studies conducted thus far suggest a variable or mixed fire regime.

The following summary of fire history in California red fir forests is paraphrased from Husari and Hawk (1993) with additional information from Taylor (1993). Estimates of natural fire frequency in California red fir range from 21 to 65 years (Taylor 1993; Taylor and Halpern 1991). Analysis of lightning fire occurrence in Yosemite National Park shows that, on a per acre basis, the California red fir forest type there experiences more lightning ignitions than any other vegetation type, but the fires are mostly small (van Wagtenonk 1986). This is probably attributable to lower overall productivity on these sites, a compact duff layer, a short fire season, and generally cool, moist conditions. The California red fir forest shows structural evidence of a combination of large intense fires, small fires and fires of mixed

reduced the spatial diversity, but the varying distribution of seed sources and sprouting shrubs in the preburn mosaic probably enhanced variability in postburn vegetation. A fire effect near the lower forest boundary was to maintain seral grasslands, shrublands, and aspen groves by periodically removing most of the invading young Douglas-fir or lodgepole pine (Arno and Gruell 1986; Patten 1963; Strang and Parminter 1980).

Post-1900 Succession—With a reduction in fire activity due to livestock grazing (removing fine fuels) and fire exclusion policies, young conifer stands have invaded former grasslands within or below the forest zone. The trees are densely stocked and subject to extreme drought stress. They often have poor vigor and are susceptible to western spruce budworm or other insect or disease attacks and to stand replacing fires. Productivity of seral herbs, shrubs, and aspen declines dramatically in the continuing absence of fire.

Stands within the forest zone may have undergone significant changes in recent decades. As a result of fire exclusion, the trees in most stands within the landscape mosaic have become older, and often have a buildup of down woody or ladder fuels. Recent wildfires have burned as larger stand-replacement fires than those detected in fire history studies (Arno and others 1993; Barrett and others 1991).

Management Considerations—Fire exclusion may move these communities toward a long-interval stand-replacement fire regime. This could decrease vegetation diversity on the landscape and may reduce values for wildlife habitat, watershed protection, and esthetics. Numerous alternatives exist for simulating more natural landscape structure and disturbance regimes using silvicultural cuttings and prescribed fire (Arno and Fischer 1995; Arno and others 2000; Brown 1989; Gruell and others 1986).

Whitebark Pine

Pre-1900 Succession—The whitebark pine type occurs near the highest elevations of forest growth from southern British Columbia south to western Wyoming in the Rocky Mountains and along the Cascades to northern California. In the drier mountain ranges and on rocky sites with sparse fuel, whitebark pine is characterized by a mixed fire regime, whereas in moist and more productive areas it is perpetuated by a stand-replacement fire regime. The mixed fire regime has been noted in whitebark pine stands in the Selway-Bitterroot Wilderness and nearby areas of central Idaho and western Montana (Barrett and Arno 1991; Murray 1996). Prior to 1900 these forests experienced a range of fire intensities from nonlethal underburns to large (but usually patchy) stand-replacement fires. Rugged terrain, including extensive

rocklands and cool-moist north slopes hampered the spread of fires and resulted in a variable burn pattern.

Whitebark pine is a seral species on all but the harshest sites and is replaced successional by subalpine fir, Engelmann spruce, or mountain hemlock (fig. 5-7). These species were readily killed in low-intensity fires, whereas whitebark pine often survived. Epidemics of mountain pine beetle periodically killed many of the older whitebark pines. Fuels created by beetle kills and successional ladder fuels contributed to patchy torching or stand-replacement burning. Underburns had a thinning effect that removed many of the competing fir, while more intense fires created open areas favorable for whitebark pine regeneration. This species' seeds are harvested and cached often in burned areas by Clarks Nutcrackers (*Nucifraga columbiana*). Many seed caches are not retrieved, so pines regenerate (Tomback 1982). Whitebark pine is hardier than its competitors and functions as a pioneer species on high-elevation burns.

Post-1900 Succession—Fire exclusion may have been particularly effective in many areas of the whitebark pine type where rugged terrain provides natural fire breaks. To cover large areas of the type, which is restricted to high ridges, fires had to burn across broad valleys. Many of the latter are now under forest management, agriculture, suburban or other development that prevents fire spread. Large wilderness areas and National Parks sometimes allow wildland fires with limited suppression as a substitute for natural fires. However, even the most successful natural fire program in a large wilderness has had a lower level of success in returning fire to whitebark pine than to other forest types (Brown and others 1994, 1995). Major fires in the whitebark pine type are confined largely to late summer in especially dry years, when prescribed natural fires usually are not allowed.

To complicate matters, white pine blister rust (*Cronartium ribicola*), an introduced disease, is killing cone-bearing limbs and entire trees of whitebark pine in about half of the species' natural range (Arno and Hoff 1990). A small percentage of the trees has some resistance, but without ample sites upon which to regenerate, resistant strains cannot develop and multiply.

Management Considerations—Fires may be more critical for whitebark pine's survival now that blister rust has inflicted heavy mortality across large areas of the Northwestern United States. Evidence from mortality observations (Kendall and Arno 1990), permanent plots (Keane and Arno 1993), and ecological process modeling (Keane and others 1990b) suggests that unless active management is carried out on a landscape scale, whitebark pine will continue to decline in a large part of its range and may virtually

Figure 5-7—Whitebark pine regenerating on a 26-year-old burn (foreground). In contrast, the old, unburned forest (background) consists of subalpine fir, Engelmann spruce, and dead whitebark pine snags.

disappear in some areas. Use of wildland fires in wilderness, prescribed fires, release cuttings to favor the pine over its competitors, and aiding the propagation of natural rust resistance are the most obvious alternatives. These measures are now being tested at several sites in Idaho and Montana by Robert Keane, Rocky Mountain Research Station, Missoula, Montana.

Ponderosa Pine

Pre-1900 Succession—Some ponderosa pine forests were historically characterized by mixed fire regimes, although the extent and ecological relationships of these mixed regimes are yet to be determined. It appears that mixed regimes were commonly associated with ponderosa pine growing east of the Continental Divide, and also with some forests west of the Divide, especially those on steep slopes and on relatively moist sites. The most compelling evidence for a large area of mixed fire regime comes from the Black Hills of South Dakota (Brown and Sieg 1996; Gartner and Thompson 1973; Shinneman and Baker 1997) and the Front Range of the Rocky Mountains in Colorado (Kaufmann 1998; Laven and others 1980). Many of the ponderosa pine stands in the Black Hills and nearby areas of northeastern Wyoming and southeastern Montana develop dense patches of pine regeneration

after fire, which become thickets of small stagnant trees, susceptible to stand-replacing fire. Intervening areas with more open stocking presumably were more likely to underburn in the frequent fires of the pre-settlement era. Factors contributing to a mixed fire regime in ponderosa pine probably include relatively moist sites that tended to produce pine thickets soon after a fire, areas frequently exposed to high winds during the burning season, steep topography, and stands killed by bark beetle epidemics.

Post-1900 Succession—In the Black Hills, northeastern Wyoming, and southeastern and central Montana, fire exclusion coupled with livestock grazing has resulted in an expansion of ponderosa pine from its presettlement habitat on rocky ridges and other poor sites into the adjacent grassy plains. This invasion may involve over a million acres (Gartner and Thompson 1973; Gruell 1983), but no data are available. The stands on the ridges have also thickened with ingrowth of younger trees. Dense stands greatly reduce production of native grasses and forbs and diminished forage values for livestock and wildlife (Gartner and Thompson 1973). Thousands of homes are now located in these dense pine stands, and many are threatened annually by wildfires. Nearly 50 homes burned in a central Montana wildfire in 1984, and over

100 burned in 1991 in ponderosa pine woodlands near Spokane, Washington.

Management Considerations—The dense stands of small ponderosa pines that have expanded into grasslands in the upper Great Plains are at high risk of severe wildfire and have diminished forage values. Breaking up the continuity of these stands using silvicultural cuttings and prescribed fire treatments would allow more effective control of fire. It may be possible to thin some of these stands commercially while retaining the largest and healthiest trees. Prescribed burning in conjunction with cutting could reduce fuel loadings and stimulate forage (Gartner and Thompson 1973; Kilgore and Curtis 1987). Initial burning should be done with care not to injure leave trees (see discussion of ponderosa pine in the section “Understory Fire Regimes”).

There may be objections to converting dense stands to open-growing ones, especially doing so on a landscape scale (Shinneman and Baker 1997). Patchy even-aged cuttings and prescribed burns are one alternative that could be used to simulate historical mixed regime patterns (Franklin and Forman 1987). Allowing dense forests on public lands to be killed by insect epidemics that encourage severe wildfires may be the eventual result of inaction. This latter alternative could be made less hazardous to adjacent lands if fuels management were carried out around the borders of such areas (Scott 1998).

Stand-Replacement Fire Regimes

Major Vegetation Types

Major forest types include coast Douglas-fir, true fir/hemlock, interior true fir/Douglas-fir/larch, Rocky Mountain lodgepole pine, white pine/western redcedar/hemlock, spruce/fir/whitebark pine, and aspen. Several minor forest types are also characterized by stand-replacement fires. These forests are widespread in wetter forest regions of the Northwestern United States and Western Canada and in subalpine forests associated with the major mountain ranges. Some of the same compositional types are also characterized by mixed fire regimes in large portions of their distributions. Differences in regional climate, fuels, and local topography can influence the resulting fire regime (for example, see Barrett and others 1991).

Fire Regime Characteristics

Stand-replacing fires kill most overstory trees, although the pattern of these fires on the landscape varies with topography, fuels, and burning conditions. Sometimes extensive areas burn uniformly in

stand-replacing fire events, especially in wind-driven crown fires (Anderson 1968). However, a major proportion of stand-replacement is caused by lethal surface fire, as was the case with much of the 1988 Yellowstone Area fires. Lethal surface fire was responsible for about 60 percent (versus 40 percent in crown fire) of the stand-replacement burning in the Selway-Bitterroot Wilderness under the prescribed natural fire program (Brown and others 1995). Under different conditions, a complex landscape mosaic of replacement burning from crown fire and lethal surface fire is interwoven with areas of lighter burning or no burning. For instance, patchy burning patterns may be accentuated by rugged mountainous topography containing contrasting site types, microclimates, and vegetation. These mosaic elements represent diverse burning environments and the result is that stand-replacement burning is restricted to certain landscape elements. For example, in one area of northern Idaho, stand-replacement fires were associated with a mid-slope “thermal belt” on southern and western exposures while other slopes tended to burn in mixed severity fires (Arno and Davis 1980). Superimposed on the site mosaic is a fuels mosaic linked to the pattern of past fires. On gentle topography and more uniform landscapes, such as high plateaus, stand-replacement fires tend to be more uniform or at least to burn in large-scale patches.

Stand-replacement fires generally occur at long average intervals (table 5-1), ranging from about 70 years in some lower elevation Rocky Mountain lodgepole pine forests subject to extreme winds, to 300 to 400 years in some inland subalpine types, and over 500 years in some moist coastal mountain forests. Often the range of actual intervals is broad since the fires themselves depend on combinations of chance factors such as drought, ignitions, and high winds. Such combinations occur sporadically. In coastal forest types having long fire intervals, such as coast Douglas-fir and true fir-mountain hemlock, it appears that exceptional drought and perhaps an unusual abundance of lightning ignitions were linked to major fires (Agee 1993). The great length of intervals and findings of substantial climatic changes during the last few thousand years suggest that fire intervals varied with climatic changes (Johnson and others 1994).

The irregular timing of stand-replacement fire is heightened in several forest types by their propensity to support double or triple burns in the aftermath of an initial fire. For instance, the Yacolt fire (1902) of southwestern Washington and the Tillamook fire (1933) of northwestern Oregon reburned numerous times (Gray and Franklin 1997; Pyne 1982). A history of occasional replacement fires followed by severe reburns also is common in the Clearwater drainage of northern Idaho (Barrett 1982; Wellner 1970).

In the Rocky Mountain lodgepole pine type, fuel buildup is an important factor in length of fire intervals (Brown 1975; Romme 1982). Mean fire intervals in this type range from a low of about 70 years in productive lower elevation lodgepole pine forests in high wind environments on the east slope of the Rockies—for example, at Waterton Lakes National Park, Alberta; Glacier National Park, Montana; and perhaps in the Red Lodge area northeast of Yellowstone National Park. At the other extreme, mean fire intervals on unproductive sites such as the high-elevation rhyolite plateaus in Yellowstone National Park are 300 to 400 years (Millsbaugh and Whitlock 1995; Romme 1982). The majority of studies in this type has found mean fire intervals between 100 and 250 years (Agee 1993; S. W. Barrett 1994; Hawks 1980; Kilgore 1987).

Fuels

Unlike understory and mixed fire regimes, fuels play a critical role in limiting the spread of fire in stand-replacement fire regimes. Accumulation of duff and down woody fuels increases the persistence of burning. This is important for keeping fire smoldering on a site until a wind event occurs (Brown and See

1981). Typically a certain level of fuel is required to allow fire to spread. This may be the result of dead and down fuels—from insect epidemics, windstorms, or a previous fire—or of extensive ladder fuels (fig. 5-8). In contrast, stands with few down or ladder fuels often fail to support fire (Brown 1975; Despain 1990). In lodgepole pine, dead and down woody fuel loadings of 15 to 20 tons/acre (34 to 45 t/ha) are generally near the lower threshold of what will support a stand-replacement through moderate-intensity surface fire (Fischer 1981). Ladder fuels and heavier loadings of down and dead woody fuels contribute to torching, and with winds a running crown fire may evolve.

In cover types supporting large trees such as Douglas-fir/hemlock and western white pine, large woody fuel loadings typically are 40 to 50 tons/acre (90 to 110 t/ha) and duff about 30 tons/acre (67 t/ha) (Keane and others 1997). In smaller tree cover types such as lodgepole pine and spruce/fir, large woody fuels typically are 15 to 20 tons/acre and duff about 15 to 30 tons/acre. However, the range in loadings may be considerably greater as reported for Kananaskis Provincial Park, Alberta (Hawkes 1979), where downed woody fuels ranged from 4 to 63 tons/acre (9 to 141 t/ha) and duff from 8 to 58 tons/acre (18 to 130 t/ha).

Figure 5-8—Downfall of mountain pine beetle killed lodgepole pine results in an accumulation of large downed woody fuels that increases the likelihood of stand-replacement fire.

Postfire Plant Communities

Coast Douglas-fir

Pre-1900 Succession—These humid maritime forests are extensive at lower and middle elevations west of the Cascades and British Columbia Coast Range. The cooler, wetter, and more northerly portions of the coastal Douglas-fir type (generally associated with the mountains of western Washington and southwestern British Columbia) burned in stand-replacement fires at long intervals, averaging 200 to several hundred years (Agee 1993). The range of pre-1900 fire intervals on a given site is unknown because in most cases only the most recent interval can be calculated due to decay of the previous stand. Long and others (1998) described fire intervals over the last 9,000 years, and Impara (1997) reports on the spatial patterns of historical fires in the Oregon Coast Range.

Western hemlock is the potential climax dominant tree in most of this type, but seral Douglas-fir, which arose after replacement fires during the last several hundred years, is the actual dominant. The greater size and longevity of Douglas-fir allows it to persist in considerable quantities for 700 to 1,000 years between major stand-opening disturbances such as fire or severe blowdowns (Agee 1993). Scattered individual Douglas-fir survived fires and served as seed sources in the burn. Seeds of this species may also survive and mature in the crowns of some trees whose foliage was killed (but not consumed) by a late-summer fire. The seeds are also wind-dispersed from unburned stands. Douglas-fir seedlings grow readily on burned seedbeds and outcompete other conifers in the postburn environment.

Often red alder becomes abundant and temporarily outgrows Douglas-fir in a recent burn. However, the fir grows up beneath and displaces alder within a few decades, benefitting from soil nitrogen fixed by symbiotic organisms associated with alder roots. Numerous other seral conifers (western white pine, shore pine, grand fir, and Sitka spruce) and hardwood species (bigleaf maple, mountain ash, cascara, and others), as well as seral shrubs (salmonberry, huckleberries) and herbaceous plants, appear in the postburn environment, greatly enriching the biological diversity of these forests (Fonda and Bliss 1969; Franklin and Dyrness 1973; Hemstrom and Franklin 1982; Huff 1984; Yamaguchi 1986).

Post-1900 Succession—Due to the great length of natural fire intervals it would seem unlikely that significant successional changes have occurred in most of these forests as a result of attempts to exclude fire during this century. Large areas of these forests have been clearcut in recent decades, sometimes followed by broadcast burning. This has given rise to large

areas of early seral communities dominated by native flora, often with planted Douglas-fir, which might offset a shortage of early seral communities resulting from natural fires. However, natural burns and clearcuts differ ecologically, for example, in seedbed preparation, in providing residual large woody debris, and in having an overstory of dead trees (Kauffman 1990). Hansen and others (1991) point out that young communities arising after fires are rich in structural complexity and in species composition, but are the rarest successional state, much rarer in today's landscapes than is old growth. Although millions of acres have been set aside as reserves for old growth Douglas-fir, there are no measures for perpetuating these communities through the use of prescribed fire, and if present fire suppression policies succeed, young postfire communities will continue to be rare.

Management Considerations—Until the 1990s these forests were usually managed by clearcutting, site preparation, and growing even-aged stands at rotations (50 to 100 years) much shorter than those of presettlement fire intervals. This management approach failed to consider perpetuation of many ecological functions in these forests (Kauffman 1990). The need to develop more ecologically-based management strategies gave rise to concepts of "new forestry" treatments (Franklin and others 1986; Gillis 1990; Hopwood 1991). Most of these leave patches of overstory and understory trees after harvesting to increase structural diversity of the new stand and the "biological legacies" of large woody debris. In this structural respect, these treated stands are simulating the early seral community following a natural fire. However, many of the proposed treatments avoid actually utilizing fire due to a desire to limit smoke, increase woody residues on the site, avoid the operational difficulties in burning, and reduce treatment costs (Means and others 1996). Douglas-fir can be regenerated in heavily logged areas without burning. It is apparently assumed that the other effects of fire are expendable, for example, in soil nutrition and maintenance of diverse fire-dependent undergrowth species (Agee 1993; Kauffman 1990). However, there is little scientific basis for such an assumption. A more rigorous evaluation of the consequences of various management alternatives, including use and avoidance of burning, is needed for this ecological type.

Coastal True Fir-Mountain Hemlock

Pre-1900 Succession—These high-elevation maritime forests are found along and west of the crest of the Cascades (north of Crater Lake, Oregon) and the British Columbia Coast Range. Principal tree species are Pacific silver fir, mountain hemlock, western hemlock, and noble fir. This type is a cooler and wetter

environment than the coastal Douglas-fir type that borders it at lower elevations and on warmer aspects. Annual precipitation is commonly >100 inches and a deep snowpack accumulates in winter and persists into early summer.

The principal tree species are fire-sensitive and seldom survive surface fires. Thus, fires were typically of the stand-replacement type, although scattered Douglas-fir found in this type often survived. Fire return intervals were evidently between about 125 and 600 years (Agee 1993). Shorter intervals (<200 years) were associated with drier environments where the type is confined to north-facing slopes and is surrounded by drier types. Fires in this type usually occur under conditions of severe summer drought accompanied by strong east (foehn) winds. Major blowdowns also initiate regeneration cycles and can contribute large amounts of fuels in this type.

Postfire stands often go through a shrub-dominated stage—commonly including early seral communities of mountain huckleberry (Agee 1993; Franklin and Dyrness 1973). A variety of early seral conifers becomes established in burns (noble fir, Douglas-fir, subalpine fir, Alaska-cedar, lodgepole pine, and western white pine). Eventually the shade-tolerant Pacific silver fir, mountain hemlock, and western hemlock become dominant.

Post-1900 Succession—The long intervals between stand-replacement fires and the remote location of much of this forest type suggest that fire suppression would have had a minor effect upon it, but no detailed evaluation of this question has been made.

Management Considerations—Few fire management programs that plan for wildland fire use exist in the National Parks and wilderness areas in this forest type. Where fires occurred in the past, they often resulted in shrubfield/open conifer stands. These persistent open, “old burn” communities have been an important component of wildlife habitat and natural diversity. Use of prescribed fire is limited in this type because fire generally burns only under extreme weather conditions. Because the principal tree species are readily killed by fire, any burning in standing trees increases loadings of dead and down fuels. Mechanical fuel manipulation (tree harvesting or removal of dead woody fuel) is necessary for creating fuel reduction zones to contain wildfires (Agee 1993).

Interior True Fir–Douglas-fir–Western Larch

Pre-1900 Succession—This is a diverse group of forests that have a stand-replacement fire regime and are dispersed throughout much of the Interior West, usually at middle elevations in the mountains. Principal tree species are white fir and grand fir (potential

climax), interior Douglas-fir (seral or climax), and larch, lodgepole pine, and aspen (early seral associates). These forests commonly develop dense stands with accumulations of ladder fuels and they often occupy steep slopes on cool aspects. The forest floor fuels are primarily a compact duff layer that does not support low intensity surface fires. However, when down woody or ladder fuels accumulate and severe burning conditions arise, they can support a stand-replacing surface or crown fire. Such fires occurred at intervals averaging between 70 and 200 years. Similar compositional types in other geographic areas or on different topographic situations are associated with mixed fire regimes. The relative amounts of these types in mixed and stand-replacement fire regimes is unknown (Brown and others 1994). Also, the factors that determine whether one of these forests will have a mixed or stand-replacement regime is not known, but lack of receptiveness of surface fuels to burning, characteristically dense stands, steep slopes, and frequent strong winds probably favor the stand-replacement fire regime. For example, one area in the stand-replacement regime is on the eastern slope of the Continental Divide in Montana where dense Douglas-fir stands develop in an environment featuring severe winds (Gruell 1983).

Relatively frequent stand-replacement fires kept much of the landscape in open areas (seral grasslands or shrublands) and favored seral shrub species (such as serviceberry, willow, and bitterbrush) and aspen. Such plant communities are important forage for wildlife.

Post-1900 Succession—Photocomparison and fire history studies suggest that fire exclusion has allowed a greater proportion of these inland forests on the landscape to develop as dense stands. The spatial continuity of these stands may allow insect and disease epidemics and stand-replacement fires to become larger than in the past (Arno and Brown 1991; Byler and Zimmer-Grove 1991; Gruell 1983) (fig. 5-1). At the same time seral grassland species, shrubs, aspen, and seral conifers are being replaced by thickets of shade-tolerant conifers.

Management Considerations—This major forest cover type is divided into mixed and stand-replacement fire regimes, but the environmental characteristics linked to each fire regime type are poorly known. Knowledge of these characteristics would help land managers determine where stand-replacement fire is probable, which might help in setting priorities for management of fuels to confine potentially severe wildland fires. It should be possible to reduce frequency and extent of stand-replacement fires using a variety of fuel-reduction treatments. Prescribed fire in activity fuels (slash) can be useful in fuels reduction

and in obtaining other desirable fire effects such as stimulation of wildlife forage. It may be possible to use fire for fuels reduction and habitat improvement for ungulates by felling a few trees per acre to create enough fine slash fuels to allow a prescribed fire to move through the stand. This is promising in Douglas-fir stands because of this species resistance to low intensity fire.

Rocky Mountain Lodgepole Pine

Pre-1900 Succession—This is a major type at middle to high elevations in the more continental mountain climatic areas of the Inland West, from the Yukon Territory, Canada, to southern Colorado. In parts of this geographic distribution, lodgepole pine forests burned in a mixed fire regime, primarily where fine surface fuels and dry climate allowed lower intensity fires to occur. Much of the lodgepole pine type, however, is resistant to burning except when there is an accumulation of down woody, ladder, and crown fuels. When fuel loadings are sufficient to support fire, it becomes a stand-replacing surface or crown fire.

Brown (1975) illustrated how fuel loadings are indirectly linked to stand age (fig. 5-9). Young dense stands containing ladder fuels of associated spruce and fir and accumulated downfall from a former, beetle-killed or fire-killed overstory have high potential to support a stand-replacement fire. Conversely, young pole-size stands of pure lodgepole pine (with sparse lower limbs) arising after a burn that removed most large fuels, have low potential to support fire. When a lodgepole pine stand becomes mature or overmature, tree growth and vigor declines markedly, and likelihood of a mountain pine beetle epidemic

increases. Such epidemics kill many trees that begin falling in a few years, and within 10 to 15 years large amounts of dead woody fuels accumulate that greatly adds to the potential of stand-replacement fire. Dwarf mistletoe also builds up with stand age and adds highly flammable witches-brooms to the tree crowns. Stand-replacement fire destroys the dwarf mistletoe, except in surviving patches, and removes potential for mountain pine beetle until a mature stand has again developed.

Post-1900 Succession—Some studies indicate that attempts to exclude fire have had relatively little effect in this fire regime (Barrett and others 1991; Johnson and others 1990; Kilgore 1987). Certainly numerous fires have been successfully suppressed while quite small or while they were in adjacent, different fire regime types; but this is presumably offset by additional ignitions from large numbers of human-caused fires. The possibility exists that suppression could have appreciable effects in some geographic areas, especially where units of this type are small, isolated, and surrounded by other kinds of forest or vegetation where fires have been largely excluded. In the southern Canadian Rockies a decline in fire frequency in largely stand-replacement fire regime types was attributed at least partially to prevention and suppression of human-caused fires (Achuff and others 1996). However, in some geographic areas, the proportion of area burned by lethal severity has increased (fig. 5-1).

Management Considerations—As illustrated by the political uproar regarding the Yellowstone Area fires of 1988, this forest type represents a challenge for fire management (Christensen and others 1989; Wakimoto 1989). Ecologists, land managers, and many environmental activists recognize the importance and inevitability of large stand-replacement fires. In contrast, such fires are often viewed as an unnecessary inconvenience or as a disaster by those who are unaware of the natural role of wildland fire.

Fires are critical to maintenance of biological diversity in this type. Many early seral species, including herbs, shrubs, and aspen, depend on occasional fires to remain as components of the lodgepole pine type (Habeck and Mutch 1973; Kay 1993). Black-backed Woodpeckers, many invertebrates, herbivores, small mammals, birds, and even some aquatic organisms depend upon fires for creation of seral communities, snag patches, and beneficial nutrient cycling (Agee 1993; Despain 1990).

Stand-replacement fire regimes in lodgepole pine forests can be influenced by management actions. For example, fuel breaks can be developed near critical property boundaries and to protect resorts and other facilities (Anderson and Brown 1988; Kalabokidis and Omi 1998; Schmidt and Wakimoto 1988). Wildland

Figure 5-9—Fuel cycles and fire intensity potential in a lodgepole pine stand-replacement fire regime (Brown 1975).

fire use programs coupled with prescribed stand-replacement fires could help develop landscape fuel mosaics that limit the ultimate size of wildfires (Weber and Taylor 1992; Zimmerman and others 1990).

Clearcutting and broadcast burning have long been a common timber management treatment in this type. If fine fuel consumption is complete, most of the seed source in the slash will be destroyed. Seeds from open-coned pines at the edge of units are often wind-distributed about 200 feet into clearcuts in sufficient quantities for forest regeneration (Lotan and Critchfield 1990). Leaving some cone-bearing trees standing throughout the burn can provide seed source as well as light shade and snags for wildlife. In salvage logging of fire-killed stands, it is important to leave ample dead trees for a variety of wildlife species.

There is increasing interest in planning for patches of trees to survive broadcast burning, to provide structural diversity in the post-treatment community (Arno and Harrington 1998; Hardy and others 2000). Underburning in a lodgepole pine shelterwood cut, although difficult, may be possible if slash fuels are light and moved away from the base of leave trees.

Western White Pine-Cedar-Hemlock

Pre-1900 Succession—This forest type is centered in northern Idaho and the interior wet zone of southeastern British Columbia (Krajina 1965; Shiplett and Neuenschwander 1994). It also extends into northeastern Washington and northwestern Montana. It occupies a “climatic peninsula” (Daubenmire 1969) or inland extension of Pacific maritime climate between about 46 and 53 °N latitude. This is the only area of the Rocky Mountain system where western white pine, western redcedar, western hemlock, and numerous other maritime associates (trees and undergrowth) are found. In this area the inland maritime species form the dominant vegetation mixed with Inland Rocky Mountain species such as ponderosa pine, interior Douglas-fir, Engelmann spruce, western larch, and whitebark pine.

Traditionally this type has been considered to mainly represent a stand-replacement fire regime, but detailed fire history studies are few (Smith and Fischer 1997). The most characteristic, large, and influential fires were stand-replacing, and because of scarcity of information, the type is discussed only in this section. Nevertheless two recent studies (Barrett 1993; Zack and Morgan 1994) as well as earlier observations (Arno 1980; Arno and Davis 1980; Marshall 1928) indicate that substantial areas of the type were also exposed to a mixed fire regime. Evidence of underburning is often found in valley bottoms, on gentle slopes on dry aspects, and on ridgetops. Surviving trees were primarily western white pine, western

larch, and large western redcedars. Underburns may have been important locally in perpetuating a dominance by large trees of these species. Conditions associated with underburning have not been described, but underburning has occurred in recent wildland fires in these forests (Brown and others 1994).

The stand-replacement fires characteristic of the western white pine-cedar-hemlock type occurred at intervals of 130 to 300 years associated with severe drought, which commonly occurred for a short period during mid- or late-summer. Because of the productive growing conditions, ladder fuels can develop rapidly in young stands. Moreover, large woody fuels are created in abundance by fires and by insect and disease epidemics. Two or three decades after a stand-replacement fire, most of the dead trees have fallen and become heavy down fuels. This, coupled with a dense stand of small trees and tall shrubs, may constitute a fuelbed that allows severe burning in a second fire, known as a “double burn” (Wellner 1970). When fire occurs under conditions of extreme drought accompanied by strong winds, stand-replacement fires are likely in many natural fuel configurations. If large accumulations of down woody fuel (>25 tons/acre) are present, stand-replacement fires can occur under extreme drought without strong winds or steep slopes (Fischer 1981).

Past stand-replacement fires allowed seral fire-dependent species to dominate most pre-1900 stands. The major early seral tree dominants were western white pine, western larch, and lodgepole pine, but were accompanied by lesser amounts of interior Douglas-fir, grand fir, Engelmann spruce, paper birch, and ponderosa pine. Including the everpresent western redcedar and western hemlock, these disturbance communities were diverse. Luxuriant seral shrub and herbaceous plant growth added to this diversity, as described by Larsen (1929), Daubenmire and Daubenmire (1968), and Cooper and others (1991). Occasional fires allowed a variety of seral shrubs to thrive, including redstem and evergreen ceanothus, currants, red elderberry, Scouler willow, serviceberry, mountain maple, American mountain-ash, bittercherry, and chokecherry. After a double burn, shrubfields would persist for decades (Barrett 1982; Wellner 1970). Shiplett and Neuenschwander (1994) classify five common successional scenarios in these forests. These are (1) a relatively rapid succession to the redcedar-hemlock climax, (2) a prolonged domination by a mix of seral tree species as a result of disturbances, (3) a shrubfield resulting from multiple burns, (4) a sere influenced by scattered larch relicts that survived fires, and (5) lodgepole pine dominance throughout fire cycles on less productive sites with relatively frequent burns.

Post-1900 Succession and Management Considerations—Clearcut logging has to a considerable extent replaced fire as the principal stand-replacing disturbance in this forest type. Often the logging is followed by broadcast burning or dozer scarification and piling of large woody residues, which are then burned. Like stand-replacement fire, clearcutting favors establishment of early seral tree species. Unlike fire, clearcutting does not leave a snag forest to moderate the microclimate and provide large quantities of woody debris and future fuels. Recently, environmental concerns have been raised about cumulative impacts of road building and logging, including soil disturbance, erosion, loss of water quality, aesthetic impacts, loss of wildlife habitat, and smoke production from prescribed fire. These concerns have encouraged substitution of partial cutting or of no cutting at all accompanied by fire suppression. These approaches contrast strongly with natural fire in their effects on vegetation and may result in epidemic forest mortality resulting from root diseases and bark beetles (Byler and Zimmer-Grove 1991).

A high percentage of western white pine has been killed in the last 50 years as a result of white pine blister rust, an introduced disease. White pine has a low level of natural rust resistance, and resistant genotypes are available for use in reforestation. However, this species requires fire or logging with site preparation to make sites available for regeneration and successful establishment.

Relatively rapid change is characteristic of the vegetation in this highly productive forest type. In the past, fire was the principal agent initiating new cycles of change. Heavy logging and site preparation was to a limited extent a replacement for fire, but had some undesirable impacts. In revising management to reduce those impacts it is important to consider strategies and treatments that provide the beneficial effects associated with fire in these ecosystems (Smith and Fischer 1997).

Spruce-Fir-Whitebark Pine

Pre-1900 Succession—This type makes up the highest elevations of forest growth in the Rocky Mountains and other interior ranges of Western North America from central British Columbia to central Oregon and western Wyoming. Southward in the Rocky Mountains to New Mexico, beyond the range of whitebark pine, the ecologically similar limber pine is often associated with the spruce and fir. In northern British Columbia, the high-elevation spruce-fir forest merges with the white spruce and black spruce boreal types discussed in chapter 3.

In drier regions of the Interior West and locally on drier topographic sites is a mixed severity fire regime characterized by an abundance of whitebark pine (see

the section “Mixed Fire Regimes” in this chapter). In contrast, the spruce-fir-whitebark pine type has variable amounts of whitebark pine or none at all, but is characterized by stand-replacement fires generally at intervals of 100 to 400 years. For example, in the most detailed study of this type so far, in the Bob Marshall Wilderness Complex in Montana, Keane and others (1994) found mainly stand-replacement fires at intervals of 54 to 400+ years in 110 sample stands distributed across a 1.5-million-acre (607,000 ha) area. In the Southern Rocky Mountains, spruce is often the dominant subalpine forest cover and other major disturbances—spruce beetle epidemics, extensive snow avalanches, and areas of wind-thrown forest—interact with stand-replacement fires in complex temporal and spatial patterns (Baker and Veblen 1990; Veblen and others 1994). In the wettest spruce-fir microsites, such as naturally subirrigated basins, fire occurs rarely and is not the prevalent factor controlling successional cycles that it is in most of Western North America.

Pre-1900 fires added structural and compositional diversity to the spruce-fir-whitebark pine forest. Burned areas often remained unforested for extended periods due to the harsh microclimate (Arno and Hammerly 1984). In extreme cases regenerating conifers take on a shrublike (*krummholz*) form for 50 years or longer. Often whitebark pine is able to become established first in a high-elevation burn due to its superior climatic hardiness and its advantage of having seeds planted in small caches by the Clark’s Nutcracker (Arno and Hoff 1990).

Post-1900 Succession—Little is known about possible human-induced changes in successional patterns throughout this high-elevation type. Logging has occurred in some sizeable areas of the type and has to a limited extent been a substitute for stand-replacement fire. In other areas fire suppression may have effectively reduced the landscape component made up of young postfire communities. For example, Gruell (1980) published many photographs taken at subalpine sites in northwestern Wyoming in the late 1800s and early 1900s and compared them with modern retakes. Most of these comparisons show that mature forest is noticeably more extensive today. Presumably the slow postfire recovery period resulted in large areas being unforested at any given time.

Whitebark pine has suffered a major setback since the early 1900s due to heavy mortality from mountain pine beetle and blister rust (Keane and Arno 1993). The introduced blister rust particularly reduces the amount of whitebark pine seed source available for regeneration. In some areas large outbreaks of spruce bark beetle and root rot in subalpine fir have also resulted in heavy loadings of large woody fuels, which will support future stand-replacement fires (Veblen and others 1994).

Management Considerations—In smaller wilderness areas and parks it is hard to plan for stand-replacement fires from lightning ignitions due to the problem of confining fires within area boundaries. Data presented by Brown and others (1994) suggest that maintaining natural fire cycles in these high-elevation forests is difficult because the forests only burn when fire danger elsewhere is unacceptably high as a result of extreme drought. Traditional timber harvesting coupled with broadcast burning is now less likely to occur because of environmental concerns about road building, watershed impacts, and obtaining prompt tree regeneration. Concerns regarding fire management options are generally similar to those expressed in high-elevation lodgepole pine types. In some cases prescribed fires might be used to maintain natural fire cycles. Cutting to provide slash fuels could allow prescribed burning to be done when wildfire hazard is moderately low.

Aspen

For discussions about aspen, see chapter 3, “Fire in Northern Ecosystems.”

Regimes Where Fire is Rare _____

In some forest types, which collectively cover only a small fraction of the forested land in Western North

America, fire is so unusual or exceptionally infrequent that it exerts little selective influence on vegetation development. Certain stands and topographic situations within the subalpine spruce-fir type seldom burn and their successional cycles are initiated primarily by beetle epidemics or windthrow. In British Columbia, Hawkes (1997) reported fire cycles of 800 to 2,000 years on cool wet sites occupied by the spruce-fir type. The only major forest type of Western North America where fire is not a primary disturbance agent is Sitka spruce-western hemlock. This type is generally confined to the wettest lowland sites along the immediate Pacific Ocean coastal strip and in alluvial bottoms of coastal valleys from southern Oregon to southern British Columbia. Northward, in central British Columbia and southeastern and south-central Alaska, it expands to cover most of the narrow, low elevation coastal forest zone (Arno and Hammerly 1984). Fires of appreciable extent are unusual in this type due to the prevalence of moist conditions year-round (Agee 1993). Windfall is a more prevalent disturbance creating new stands. On the Alaskan coast most fires are human-caused and occur during rare droughts (Noste 1969). Lightning fires are rare; nevertheless, the historic role of fire is not fully resolved. For example, Harris and Farr (1974) report four episodes of extensive fires in southeastern Alaska between about 1660 and 1830.
